In the pathogenesis of appendicitis greater importance should be given to three special conditions, rather than to the presence of lymph nodes. These conditions are:

First, the position of the appendix in relation to the large intestine, which position favors stagnation, the appendix being like a trap in the waste drainage of plumbing.

The second condition is the presence of the Lieberkühn glands, whose epithelium is so differentiated that, once destroyed, it is not reproduced, but is substituted by connective tissue.

The third condition is the constant presence in the appendix of small foreign bodies of carbon and iron, whose acute sharp edges wound and destroy the epithelium of the glands.* These limited areas of destruction of the mucosa are very frequent and numerous, and, on account of their smallness, have not been considered pathological. Although small, they are nevertheless pathological lesions.

Histologically the appendix is formed exactly as the large intestine, and we find in it the same elements in the same disposition; mucosa with Lieberkühn glands, submucosa with lymphoid follicles, areolar tissue, muscularis divided in two layers, circular and longitudinal, serous coat.

For my purpose it is sufficient to call attention to some peculiarities of the mucosa and submucosa, as these two elements are the most important in the disease. In the normal appendix of young subjects all the mucosa is occupied by the Lieberkühn glands. These tubules are disposed very regularly and the chorion between the tubules is very thin. The fundus of these glands rests on a layer of muscular fibers (muscularis mucosæ). This muscular layer separates the mucosa or Lieberkühn glands from the submucosa containing the lymphoid follicles.

The muscularis mucosæ follows the changes that happen in the mucosa. If the mucosa becomes thinner this muscular coat contracts toward the lumen of the appendix and if the mucosa enlarges the muscularis stretches toward the serosa, so much that sometimes it ruptures and its fragments retain the direction of the enlarged mucosa and remain as a line of separation between the mucosa and submucosa. The dimensions of the follicles or lymph nodes vary according to the individual.

In conclusion, in transverse sections of the normal appendix we find that the mucosa is made exclusively of the Lieberkühn tubules, and that the mucosa, the muscularis mucosæ, and the submucosa containing the lymph nodes form three concentric rings limiting the lumen of the appendix.

But this ideal disposition is very rare. The Lieberkühn glands are very often wounded by the sharp edges of the particles of carbon found constantly in the lumen of the appendix.

If the traumatic lesions of the mucosa become infected they give origin to necrotic appendicitis. But more frequently the lesions remain aseptic and heal with the formation of connective tissue. The different appearances of the lesions found in chronic appendicitis are due to the various stages of evolution of this connective tissue.

The traumatic lesion is first followed by a great infiltration of round cells taking place in the chorion of the mucosa, and in consequence the mucosa increases in volume and the muscularis mucosæ is seen stretched toward the serosa.

Later on, the formation of connective tissue progresses so that the mucosa is made thinner, and the

*C. Savini: "Microscopical Traumatic Lesions in Appendicitis," Medical Record, Nov. 28, 1914.

muscularis mucosæ is seen contracted toward the lumen of the appendix.

In time the mucosa becomes more atrophic, the Lieberkühn glands entirely disappear, and the lymphoid follicles are seen protruding into the lumen

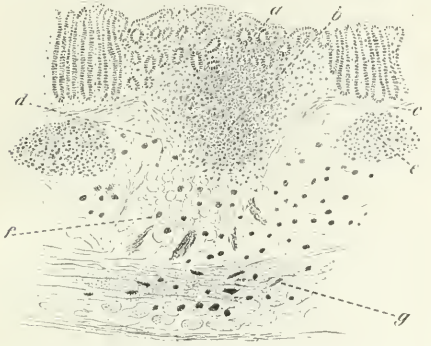

Fig. 1.—a, Infiltration of the mucosa; b, the same infiltration proceeding toward the submucosa; c, muscularis mucosæ; d, fragments of the muscularis mucosæ ruptured; e, lymphoid follicle; f, mastzellen; g, special fusiform appearance of mastzellen.

of the appendix. The lymphoid follicles appear enlarged, but their enlargement is more apparent than real and is in great part due to the atrophy of the glandular layer of the mucosa.

The lymphoid follicles protected only by a thin layer of connective tissue are brought now into contact with the foreign bodies collected in the lumen of the appendix and in their turn are wounded and destroyed.

The same sequence of pathological processes that we saw following the destruction of the Lieberkühn glands now follows the destruction of the follicles—round cellular infiltration and formation of connective tissue.

The last consequence is the atrophy of the mucosa and submucosa with the entire destruction of all the Lieberkühn glands and of all the lymphoid follicles resulting in atrophic or obliterated appendix.

All these different stages of cicatrization occupy very limited parts of the mucosa and of the submucosa and are found in different degrees in the same appendix.

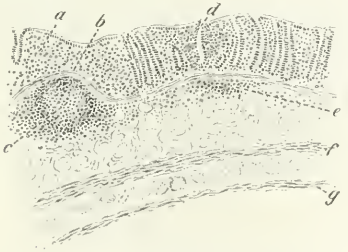

Fig. 2.—a, Repair of an old lesion of the mucosa; b, muscularis mucosæ; c, lymphoid follicle; d, traumatic lesion of the mucosa; e, collection of small round cells in the lymphatic spaces of the submucosa; f, muscular coat of the appendix; g, serosa.

We may find in the same section the traumatic initial lesion, the repair of another lesion, and an old scar, consequence of an older lesion. In this case we should not consider that all the lesions found in the section have the same importance or are the result of only one process. Or it may happen that we find only the follicles hypertrophic, wounded, and rupturing into the lumen of the appendix. But in this case we must remember that this lesion was preceded by a destruction of the mucosa.

Fig. 3.—a, Repair of an old lesion of the mucosa; b, lymphoid follicle brought toward the lumen of appendix by the contraction of the connective tissue substituting the mucosa; c, muscularis mucosæ; d, muscular coats of the appendix.

The combination of different stages of the same lesion is characteristic of the anatomical finding in chronic appendicitis. Chronic appendicitis anatomically should be considered as the succession of healing of numerous recurrent microscopical aseptic traumatisms of the mucosa and submucosa.

This schematic description of the disease is derived from the observation of the anatomical lesions found in appendicitis, combined with the clinical observation of the patient. This combination has the value of an experiment in explaining the pathogenesis of appendicitis. The history of the patient and the clinical symptoms have an importance certainly not inferior to the anatomical findings. Besides, no anatomical lesion, no matter how small, has been overlooked. Each lesion has its bearing in explaining the process. In my opinion the small lesions of the mucosa up to now have not been sufficiently considered. It seems to me that the power of repair deserves also the same amount of con-

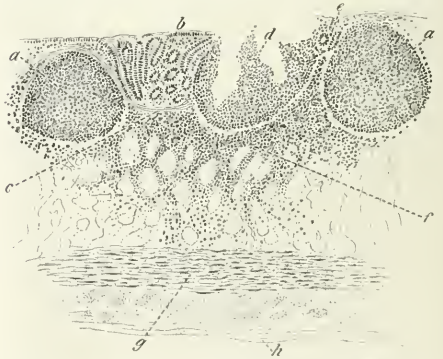

Fig. 4.—a, a, Lymphoid follicles; b, mucosa partially altered and infiltrated; c, muscularis mucosæ; d, lymphoid follicle wounded; e, remnants of Lieberkühn glands; f, infiltration of submucosa; g, muscular coats of the appendix; h, serosa.

sideration that we accord to the presence of pathogenic bacteria.

I will report here briefly the description of the lesions found in some cases operated upon by me in the Washington Square Hospital.

Case I.—A young woman was admitted to the hospital on August 14, 1914. A short time before she had suffered with an acute attack of appendicitis from which she had recovered. She was advised to be operated upon as a prevention of a recurrence. It was a case of interval operation. Operation August 15, 1914; recovery. At the macroscopical inspection the mucosa is found partially affected. The serosa is hyperemic, the mesentery thickened.

Microscopical examination (Fig. 1). A transverse section shows destruction of the Lieberkühn glands in the place of the lesion, the mucosa is infiltrated with a great number of small round cells; a layer of epithelial cells covers the lesion. The part of the mucosa so infiltrated is thicker than the remaining normal mucosa. The fibers of the muscularis mucosæ in the vicinity of the lesion are also infiltrated and almost dissected by small round cells. This muscularis is ruptured and its fragments are directed toward the submucosa. The lymph nodules near the lesions show a vigorous proliferation of cells. It seems as if the infiltration occupies all the space from the lumen of the appendix toward the lymphoid follicles, taking the follicles in it. All the other layers of the appendix, submucosa, muscularis, and serosa are infiltrated with large polynuclear cells containing round basophilic granulations. They have the appearance of mastzellen. These cells are numerous and sparsely disposed; they acquire a special fusiform appearance at the level of the muscular coat of the appendix as if they were compressed in the spaces between the muscular fibers.

Case II.—A man 30 years old was admitted to the hospital on October 21, 1912, affected with acute appendicitis of very short duration. A few months before

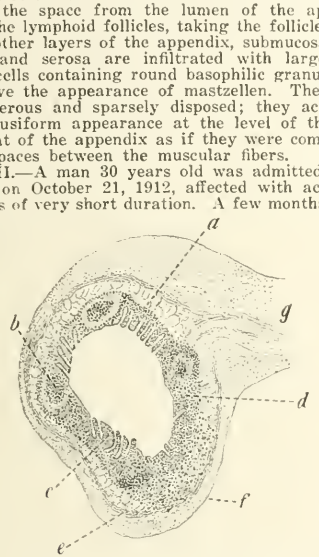

Fig. 5.—a, Normal mucosa; b, lymphoid follicle; c, mucosa partially altered; d, mucosa totally destroyed; e, muscular coats of the appendix; f, serosa; g, mesentery.

he had suffered another attack, from which he recovered. He was operated upon on the day of admission and made a normal recovery.

(Fig. 2.) At the microscopical examination of the specimen incidentally we notice a traumatic initial lesion of the Leberkühn glands, sign of the new attack. But for our scope it is more interesting to observe that in another part of the section the musoca is substituted by connective tissue which represents a stage more advanced of a lesion similar to the lesion observed in Case I. The infiltrated mucosa has already contracted, the tissue has become more condensed and compact, and its volume is reduced. The space between the follicle and the lumen of the appendix is thus diminished. The muscularis mucosæ in this place is contracted toward the lumen of the appendix.

Case III (Fig. 3.)—Represents still a more advanced step of a lesion similar to the lesions observed in Case I and Case II. The patient was a woman, operated upon January 20, 1913, for gallstones, and the appendix was removed because found affected; recovery.

Case IV.—A young woman, operated upon August 17, 1914, for acute appendicitis. History of other attacks; uneventful recovery. (Fig. 4.) The mucosa is almost completely destroyed and the lymphoid follicles brought near to the lumen of the appendix. One follicle is ruptured into the lumen of the appendix. It is most probable that the lesion in the follicle is of the same traumatic nature as the lesion found in the Lieberkühn glands of Case II. We notice also that other follicles are separated from the lumen of the appendix by a very thin layer of connective tissue which substitutes the old mucosa and is a sign of a progressive destruction of the mucosa.

Case V.—A man 35 years old, suffering with chronic appendicitis was operated upon January 29, 1914, and

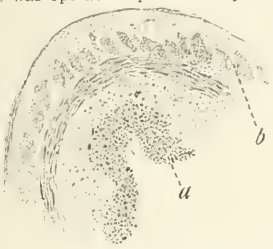

Fig. 6.—a, Connective tissue substituting the totally destroyed mucosa and submucosa; b, muscular coats of the appendix.

recovered. (Fig. 5.) One section of the appendix shows the mucosa in almost all the different stages of destruction.

Case VI.—A woman 45 years old, operated upon April 8, 1914, for chronic appendicitis with severe gastric symptoms; recovery. (Fig. 6.) At the examination the mucosa and submucosa are seen completely destroyed and totally substituted by connective tissue.

Case VII.—A man 35 years old, operated upon October 22, 1913, for chronic appendicitis; recovery. (Fig. 7.) All the appendix is found obliterated, no lumen remains. In this case some corpuscles of carbon are found encapsulated by the connective tissue almost in the center of the preparation as the only sign of the previous existence of a lumen in the appendix.

In all cases I have always found present in the lumen of the appendix the foreign bodies of carbon and iron.

Conclusions.—The pathological process of chronic appendicitis is the result of a wound of the mucosa of the appendix which has remained aseptic either by reason of special immunity of the patient or by reason of special conditions in the appendix.

It is very difficult to establish the immunity of the patient.

The special condition of the intestine can be attributed to the acidity of the contents of the large intestine and the appendix. We know that the normal reaction of the large intestine is acid, the acidity being due to the formation of lactic acid consecutive to the fermentation in the intestine.

In five cases of necrotic appendicitis I found the reactions of the contents of the appendix to be alka-

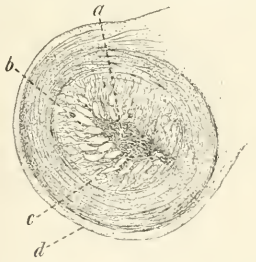

Fig. 7.—a, Central scar representing the mucosa, the submucosa, and the lumen of the appendix; b, areolar tissue; c, fibrous circular ring replacing the muscular coats of the appendix; d, serosa.

line. But this research has been limited to a number of cases too small to be authoritative. If this fact could be proved we could have a clearer idea of the pathogenesis of a great number of cases of appendicitis. Therefore the traumatic lesions of the

mucosa should be considered the starting point of appendicitis. When these lesions become infected necrotic appendicitis is the result. When these lesions remain aseptic we have chronic appendicitis.

In the pathogenesis of necrotic appendicitis the pathogenic bacteria are of the first importance. The process of repair is the most important factor in the pathogenesis of chronic appendicitis.

31 Washington Square West.

THE BUGBEAR OF DRUG ERUPTIONS.

By WILLIAM P. CUNNINGHAM, A.M., M.D.,

NEW YORK.

ASSISTANT DERMATOLOGIST, HARLEM HOSPITAL DISPENSARY; CLINICAL ASSISTANT, NEW YORK SKIN AND CANCER HOSPITAL.

Much has been written of drug eruptions. Many elaborate pen pictures and many obscure camera pictures have been published from time to time for the enlightenment of the practitioner upon these important eccentricities of the skin, with the net result of profound bewilderment and doubt. Let him recall any of the photographs he has sedulously scanned with the grim determination to master their indeterminate details, only to abandon the exasperating task in blank despair! Let him recall the minute descriptions he has read, penned with the painstaking accuracy of the scientific observer only to emerge therefrom in a state of utter stupefaction. He is reasonably lucky if he retains at this point his rudimentary grasp of bromide and iodide acne. This is in the very nature of things. It is impossible to represent the characteristics of a drug eruption in a black and white illustration. Little besides outline can be portrayed in this manner. Verbal representations are usually unconvincing because, being written by men familiar with the minutiæ of the subject, they are too detailed and circumstantial for the man who is groping his way. If something can be done to get this subject before the busy doctor in a way to avoid these drawbacks, a substantial service will have been rendered; for these drug eruptions are numerous and deceptive. If encountered and misapprehended, no results whatever of a favorable sort can be achieved. The cause continuing to operate, there will be a steady persistence or aggravation of the dermatosis, until the doctor through accident or expert assistance, makes the disconcerting discovery that it lay right under his hand and was removable at any stage of the proceedings. This is a humiliating situation, for the laity do not appreciate the difficulty involved in making the diagnosis, and mercilessly discredit the unfortunate practitioner!

To attempt to do what has so often failed at the hands of erudite and eminent observers may arouse the charge of arrogant presumption. But this would be unfair; for I maintain that failure to impress and enlighten the average medical reader has been due to failure to get his angle of observation. If you are seeking to impart information to an elementary class in astronomy you will not plunge into the intricacies of differential calculus. Much essential truth may be imbibed to the exclusion of interesting but unimportant details. A man who has not been a general practitioner, who has begun and maintained his professional activities within the confines of a special department, cannot appreciate the mental attitude of the other toward his scientific lucubrations. They are over his head and he is swamped. And this implies no disparagement of the American general practitioner. It is a natural situation in which one brain cannot comprehend all the involutions of a dozen specialties. I feel that, shorn of excess refinement, this subject can be presented in a form to be readily grasped and retained.

Drug eruptions have two constant characteristics. They appear suddenly and always in connection with the taking of drugs. That second phrase may sound like stilted vapidity, drug eruptions being necessarily dependent on the taking of drugs. But the importance of its emphatic inculcation lies in the fact that its purport is so often ignored and the eruption attributed to something else. If in every case of skin condition involving any obscurity the doctor would interrogate the patient regarding the taking of drugs, he would often get on the trail of a gratifying discovery. In fact it should be made a point of routine investigation no matter how plain the case appears to be.

Suddenness of appearance will need a little qualification. It does not mean that the eruption will always appear at once after the administration of the drug, but that on a hitherto perfectly normal skin there will be a sharp and decided outbreak inexplicable on any ground in the patient's general condition. For example a young woman with a clear complexion, unaided by artificial expedients, will one day present several acne pustules in full maturity. Nothing out of the ordinary has occurred in the routine of her existence. Her functions are normal. This distressing disfigurement is unfathomable. You proceed to treat her on the lines for acne vulgaris and you get absolutely no result. Finally, and probably through the intervention of Providence and not your own brilliant cerebration, you stumble on the insignificant and almost forgotten circumstance that she has been using a cough medicine for a slight cold, and on ascertaining the composition thereof you receive the illuminating information that it contains bromide of ammonium! The amount may be trifling, but is rendered noxious by the patent's idiosyncrasy. The etiology of these cases is frequently further obscured by the peculiar tardiness of the eruption in responding to the irritating medicine. It may not come out for days or weeks after the medication is begun. In point of fact it may not come out until the medication has been suspended, thus apparently leaving no connection between the two. If bromide has been administered within a compass of several weeks its causative relation should be taken into account. Once this is established or even suspected, there is no likelihood of mistaking these lesions, whether they invade the face, scalp, chest, back, arms, or legs, or all these localities combined.

The acneiform manifestation of cutaneous bromism is the commonest and least important of its effects. In some individuals there would appear to be a sort of malignancy in the outbreak, as evidenced by aggregations of pustules into carbuncular masses; papillomatous tumors studded with minute abscesses; verrucous outgrowths rimmed with abscesses and fixed in a deep wide zone of infiltration; pulpy flat condylomatous lesions, purplish or brown, many or few, arranged in strings, groups, or cordons, and revealing gaping follicular openings or pointing pustules. These appearances are mystifying, as a rule, until the idea of "drug eruption" flashes across the mind, whereupon the problem is solved as if by magic. In this description of the unusual and virulent assault of bromine on the skin, certain distinguishing features stand out with di-

agnostic clearness; namely the purplish or brownish color, the pulpy consistency, and the sluggish pustulation. Even the verrucous manifestations are soft to the touch. Sometimes the attack may be unique in a double sense. This apparent contradiction in terms is explained by the circumstance that the eruption may be confined to a single lesion and that that lesion may be remarkably large. It is usually located on the leg. If carefully studied it will be found to possess the dominant characteristics appertaining to all bromine eruptions, viz., it is purplish, pulpy, and pustular. The key to the varied phenomena of cutaneous bromism is that it is a pustular dermatitis, whether it appears as isolated pustules of the acne sort, or as conglomerate masses of the same, or as a papillary hyperplasia thickly studded with these primary lesions. This symptomatic quintad "purplish, pulpy, pustulated, abrupt, and drug-associated" will make out a clear case to any careful investigator. Where the pustular element is not apparent it may be evolved by the application of any irritating treatment. Bromine dermatitis has been dealt with thus at length because it is the most frequent and in its outré expressions the most puzzling of the drug-engendered lesions of the skin.

Iodide eruptions come next in order of frequency and importance. The usual manifestations are similar to those of bromide, namely a pustular acne involving face and body. Here as in the bromide eruption the absence of comedones should arouse the suspicion that we are dealing with something besides ordinary acne. Iodine may also produce lesions like the rarer ones of bromine. But in certain susceptible individuals it will develop a furious crop of enormous bullæ of all sizes and shapes, displaying in the most exaggerated form the picture of erythema multiforme bullosum. These bullæ may be as large as eggs; one of them may envelop the entire ear. They may be crescentic, oval, circular, or angular. One smaller bulla may be encircled by a chaplet of larger ones illustrating the condition known as herpes iris. In cachectic individuals these bullæ may be followed by ulceration, pyemia, and death. Any physician who administers iodides (say for the reduction of strumous adenitis) may find himself confronted with this horrifying phenomenon. It is well to be guarded in the use of this remedy, especially in children. The extreme results are not very frequent, it is true, but, occurring once, they will effectually quash all our enthusiasm for this universally employed resolving agent. Of course in luetic conditions demanding vigorous action, the risk must be run of these untoward remote effects; but here we are somewhat more advantageously placed than our predecessors, because we may have recourse to symptomolytic salvarsan in many of our cases. And while salvarsan is demonstrably no specific for syphilis, its effectiveness as an emergency remedy and surface cleanser cannot be gainsaid. It is questionable also whether the iodides have any real effect in struma and their administration to children, who are especially susceptible, is a matter of doubtful expediency.

The combined administration of the bromides and the iodides, as is often practised in cases of spasmodic bronchitis, exaggerates the tendency to the production of the ill effects of both.

In this day of the universal employment of antitoxin in the treatment of diphtheria every physician is familiar with the erythematous and urticarial eruptions consequent theron.

The newer methods of managing gonorrhea have not utterly displaced those heretofore in vogue and the morbilliform eruption of cubebs and copaiba is occasionally encountered. If this occurs in the experience of the physician who is treating the gonorrhea the etiology will be manifest. But if it is presented for diagnosis to a different physician and if the patient after the manner of his kind, and heaven only knows upon what impulse, withholds the information that would clear up the situation, then an active course of zealous mistreatment may be instituted. A rash of this character will appear suddenly, without antecedent constitutional symptoms, and accompanied by decided itching. This should serve to distinguish it from measles, the only exanthem with which it is apt to come in conflict. The abrupt onset and the lack of constitutional disturbance should limit the field of inquiry to the toxic dermatoses, and a question or two should elicit the determining confession.

It should be carefully borne in mind, however, that cubebs is occasionally administered for other pathological conditions than gonorrhea, and the nauseous suspicion of unchastity does not necessarily attach to an elderly patient of good repute who may present the eruption. For instance it still appears in some prehistoric cough mixtures and in cigarettes and powders to be used in asthma.

The analgesic action of the coal-tar preparations has merited for them a pronounced popularity. With all our croaking about the danger of these various derivatives of the gas-house rubbish heap, they are exceedingly helpful upon occasion, and if rationally employed give no cause for alarm. Incautiously administered, however, they are liable to produce disquieting symptoms in certain individuals. We are all familiar with the cardiac depression and cyanosis occasionally observed. Fortunately they frequently expend their toxicity on the skin and set up an efflorescence of the most irritating character. The percentage of outbreaks is undoubtedly small, but remembering the extensive use of these remedies both in prescriptions and proprietary medicines the aggregate is large. They all act pretty nearly the same. There will be a vivid efflorescence like scarlet fever, or a duskier patchy one like measles, or a distinctly infiltrated one like urticaria, or a crop of vesicles and bullæ either alone or interspersed with the other characters just enumerated. They really constitute a toxic erythema and the variety of the lesions corresponds to the intensity of the cutaneous reactions. Just as in a burn the bullæ or blisters follow a graver traumatism. All these lesions itch and burn depending on the degree of cutaneous reaction and the nervous irritability of the subject. They follow the invariable rule of drug eruptions, in abruptness of onset without apparent cause. And these particular drugs differ somewhat from the bromides and the iodides in making their presence *quickly* felt. One dose is apt to create a storm of trouble almost immediately.

There are many people with a marked idosyncrasy to quinine. This is usually displayed in nervous hypertension, and tinnitus aurium. Some impressionable subjects, however, have the disagreeable effects confined to the skin. A scarlatinal flush with a sense of heat or a furious attack of urticaria with exasperating pruritus are the disturbances generally experienced. The almost universal employment of this drug in the routine of medical practice makes it inevitable that such dermatoses shall be encountered from time to time by every physician.

The rule for detecting all the other drug eruptions will prove as serviceable here—namely, sudden onset and lack of preliminary phenomena.

We are all aware of the activity of belladonna in dilating the capillaries of the skin. The accompanying dryness of the fauces and the extreme dilatation of the pupils are of great assistance in establishing the etiology.

Morphine induces in most of its partakers an intense pruritus, without discernible lesions. Sometimes it will single out an unusually sensitive victim and splotch him with an erythematous morbilliform or urticarial outburst. Contracted pupils and a sweaty skin should aid in coming at the right solution; the intense itching of the end of the nose should also direct suspicion in the proper direction.

Salicylate of sodium, one of the most valuable drugs in our pharmacopœia, is sometimes productive of a disagreeable dermatosis which is none the less noteworthy because of its rarity. One can never predict the vulnerable individual and it is well to store away for ready reference in an emergency the fact that an erythematous morbilliform, bullous, or purpuric eruption may follow the administration of this remedy. This is of serious import because so many ills are attributed to the rheumatic diathesis that the dermatosis is likely to be misinterpreted and the mischievous medication pushed with the idea of bringing it under control. All of the compounds of salicylic acid, under whatsoever title and with whatsoever pretensions exploited, will produce in the susceptible patient precisely the same disturbance as the salicylate of sodium. The salicylic acid is the offending element and it is present in every one of the fancifully-styled and widely-advertised substitutes for salicylate of sodium.

Arsenic after long continued use may produce pigmentation of the general surface and keratosis of the palms and soles. This keratotic condition may form the basis of epitheliomatous degeneration. This deplorable result has been many times observed. Herpes zoster has developed often enough in the course of arsenical medication to establish an etiological connection. Its faculty of causing peripheral neuritis is the explanation. There may be, as we have noted, after the ingestion of any of the heretofore enumerated toxic agents an erythematous morbilliform or urticarial rash, or even a bullous or purpuric one. As a matter of fact, the drug rash is a toxemic manifestation just like that of intestinal origin and its varieties correspond exactly to those of erythema multiforme. There may be sheets, patches, papules, wheals, vesicles, bulæ, or purpura, depending on the degree of toxemia and the individual reaction thereto. Mental fixation of this important generalization will assist materially in the simplification of this whole problem.

A great deal of confusion and diffidence has been aroused by the delusion that every drug in the pharmacopœia had a special and distinct toxicodermatitis. The infinity of detail scared off the average investigator. Realizing that all of these cutaneous irritants acting through the vasomotor nerves produce, with few and distinct exceptions, pretty nearly the same results varying with the intensity of the dose and the vulnerability of the patient, the proposition crystallizes into a readily apprehended, stable, and harmonious whole. The essential factors in the diagnosis are not the *appearance* of the eruption so much as the *time* and *manner* of its appearance. "Scarlatiniform, morbilliform, urticarial, bullous, purpuric"; these distinctions are of little practical moment, as any one of the drugs is capable under diverse circumstances of producing all of them. An abrupt invasion under any of these aspects is suggestive of a toxic cause and it is only necessary to follow that lead to discover what the particular agent is in any given case. As we have noted, in passing, the bromides and iodides differ from the other drugs in producing *pustular* lesions. Ergot may do the same. These are caused by the involvement of the follicles and the secondary infection of their open mouths, as in ordinary pustular acne. There is no way in which these agents could induce the suppuration save by preparing the ground for the pus organism. The conglomerate lesions, constructed of these pustular units and sometimes massed into enormous verrucous, papillomatous, and sarcoma-like excrescences, are diversified by the character of the inflammatory reaction. We are all acquainted with the sluggish dermatitis that surmounts the outward orifice of a scrofulodermatous sinus. It is dull, purplish, pulpy, and indolent; a parallel to the sluggish dermatitis aroused by the bromine irritation.

The long continued use of nitrate of silver produces a bluish discoloration of the skin called argyria. Naturally this is very rarely observed owing to the infrequency of the internal administration of the salt, which is undoubtedly of value in epilepsy but has been discarded on account of this very undesirable and permanent pigmentation. Now, however, a word of caution is in order. While the nitrate of silver is scarcely ever administered by the *mouth* it is very frequently administered by the *rectum*. It is used in mucous colitis to flush the bowel in weak solutions and with the expectation of its being promptly ejected. Obviously some of it will be retained or it can give no results. Persistently used over an extended period it has brought about the same lamentable condition of the skin. It behooves us, therefore, to limit the application of this admittedly efficacious remedy to a very short trial. (Since this was written two cases of argyria following the use of nitrate of silver as a swab to the throat were presented at the Academy of Medicine.)

Chloral is widely and wisely employed in acute insomnia and nervous disturbances of short duration, such as the active delirium of alcoholism. In certain cases it will produce the same litany of dermatoses that has become familiar from constant repetition; namely "scarlatiniform, morbilliform, urticarial, vesicular, and bullous." The chloral habitué is apt to develop a chronic congestion of the face, neck, and ears which, taken in connection with mental hebetude, is quite distinctive.

It may be a matter of interest to learn that there is not a drug in the hands of the practitioner that has not its predestined victim. Even such a bland reconstructive agent as cod-liver oil, may ravage the skin of its luckless imbiber. The staid old standby of the infancy of medicine, the nearest approach to a panacea that we possess, homely, honest, dependable castor oil, will occasionally amaze us by acting likewise. Boric acid has a tremendous vogue among the general and special surgeons and dermatologists. It is regarded as an utterly harmless remedy with very decidedly efficacious action of a sedative and cleansing character. It is not usually administered by the mouth except in gargles and other local applications. It is occasionally prescribed for cystitis by this route, however, and a

very excellent remedy it is in the chronic malodorous variety. In the language of the day, hexamethylenamin "has nothing on it" as a bladder disinfectant. Once in a while—a very long while—it will set up a dermatitis, adhering to one of the types so often mentioned. Even the trifling amount absorbed from the accidental swallowing of a portion of a mouth wash has had this unfortunate effect in a patient with a pronounced idiosyncrasy. Borax, being a compound of boric acid, has displayed the same pernicious activity. The internal therapeusis of iodoform is confined almost exclusively to dermatological practice where it sometimes renders excellent results in lupus erythematosus. A dermatitis of the usual drug type is an uncommon but deplorable concomitant.

The National Formulary might be ransacked in vain for a potential medicinal agent which could be pronounced absolutely and always innocuous. Sooner or later in the course of its administration the unexpected will eventuate and another drug eruption be added to the plethoric ensemble. It will be hardly necessary to swell the enumeration, as the caution of eternal vigilance has been sufficiently urged.

All that has been discussed so far has had to do with the effect on the skin of medicines administered internally. This is styled "dermatitis medicamentosa." For convenience of classification, a purely arbitrary distinction in terms has been established between this and the effect on the skin of medicines applied externally. The latter is styled "dermatitis venenata" literally "poisoned dermatitis." Both are properly considered under the head of "drug eruptions." As an example of how the same agent may produce both the one and the other pathological condition let us consider the action of iodine. We have seen that in a pliant individual, iodine taken by the mouth will produce a violent eruption on the skin in the form of vesicles and bullæ, constituting a dermatitis medicamentosa. In the same individual iodine applied externally will do the very same thing, constituting a dermatitis venenata. Arsenic taken by the mouth will eventually induce a dusky pigmentation of the skin or even localized keratoses, constituting dermatitis medicamentosa. Arsenic applied to the skin will produce a tremendous inflammation with sloughing, constituting dermatitis venenata. The inflammatory agent in both methods of attack is the same, but the result is placed in a different category for convenience of description. It would be just as exact and scientific to say that one mode of attack produced a dermatitis medicamentosa ab. internis, and the other a dermatitis medicamentosa ab. externis. Or dermatitis venenata with the qualifying adverb might be employed for the same purpose. But usage has sanctioned the distinction in terms arbitrarily established, and there would be no practical advantage in disturbing it.

There is not nearly as much likelihood of dermatitis venenata being misapprehended as dermatitis medicamentosa, because the sequence of events is sharp and convincing. If a man puts mustard on his chest and sets up a dermatitis, there is no mistaking the provocation. If a man applies blue ointment for pediculosis pubis and achieves the same result the causative relation is just as obvious. If in the golden summer time one is lured by the call of the woods, and luxuriously reposes on a bed of moss in some romantic wild, the swollen visage of the morrow will bring conviction "strong as proofs of Holy Writ" that he has been in touch with *Rhus toxicodendron*. Instance after instance might be cited of the indisputable liaison of cause and effect in this relation. But occasionally the concatenation of circumstances is a little obscured, and there may be some difficulty in establishing it. Exempli gratia: a lady in her forties or may be in her thirties will present herself with a dermatitis of the face, neck, arms, or even most of the cutaneous surface. For reasons best known to patients and inexplicable on any ground of the slimmest common sense, the sufferer keeps her own counsel and lets the physician flounder around in a vain quest for a cause and an adequate remedy. If she would confess that she had been using a hair dye to stay the visible ravages of time, or if the physician were alert enough to note the dissonance between the raven locks and the sulci in her cheeks, a flood of light would burst upon the whole situation and the proper course of action be immediately begun.

The aniline dyes in shirts, socks, and mittens is responsible for a good many attacks of dermatitis. The association should be positive under these circumstances, but the problem is sometimes complicated by the fact that the dermatitis may spread to regions far removed from the site of the irritant. For instance a pair of nice red mittens on the hands of a child may affect not only her hands but her face or even the greater part of her surface. It is believed that there is absorption and an invasion of distant parts from within, strictly speaking a dermatitis medicamentosa, secondary to a dermatitis venenata. Results that follow immediately the application of any unusual substance to the skin will be properly interpreted in almost every instance. Arnica, iodoform, bichloride of mercury, sulphur, turpentine, cantharides, blue ointment, chrysarobin, etc., usually leave a trail that the dullest eye can follow. It is when the exciting cause is not something out of the ordinary; when it is a thing that a person is used to having in contact with the skin, such as undergarments, soap, veils, pillow cases, sheets, blankets, fur pieces, fancy collars and ruffs, that the connecting link is apt to be overlooked.

Frederick S. Dennis ascribed his phenomenal success as a teacher to the talismanic phrase "Let us repeat." At the end of one of his lectures the dullest hearer had absorbed much valuable information. Fortified by such an illustrious example I will venture to reiterate what would seem to be already adequately urged; that the diagnosis of a drug eruption with few and well defined exceptions does not rest upon the form which it assumes, as nearly all of them may assume any form, but upon the abrupt and diffused onset without apparent cause. This applies of course to eruptions from within. Most of the external causes are easy to trace. Failure to do so is attributable in most cases to a want of thoroughness in the interrogation. It should be made a routine procedure in every dermatosis, to discover everything about the habits of the patient and everything out of the ordinary that has taken place. This comprehensive inquiry will leave no loophole for the escape of important data; save only in the case of the purblind hair dyer who would seek relief from her dermatitis without revealing the cause. Actuated by vanity or the hope that the consequences can be controlled with the cause still in operation, such a patient may deny the impeachment. But once suspicion is aroused the confirmation can be obtained by the

manifest incongruity of titian, brown, or dusky locks, crowning a set and seaming visage.

It is to be hoped that something has been said to put the drug eruptions in a light to clear them of much of their confusion. The writer remembers when their apparently endless variety appalled and stunned his staggering memory and how thankful he would have been to any compassionate deliverer.

The treatment is simplicity itself; stop the irritant. If need be apply a soothing lotion for a few days to help along. The results are gratifying to everybody concerned except the hair dyer and the epileptic. The self-esteem of the one and the nervous system of the other may suffer from the plan adopted. The first consideration is a negligible one. The second is of graver import, and it may be necesary, in weighing all the circumstances, to determine whether it may not be wiser to tolerate the dermatitis than the aggravation of the neurosis. Some maneuvering may be required to strike a tolerable balance between the two. Where the iodides are toxic use salvarsan.

323 West Fourteenth Street.

THE DANGERS OF IMPURE AIR.

By HORACE GREELEY, M.D.,

BROOKLYN, NEW YORK.

While sanitary housing conditions are supposed to be largely dependent upon cost consideration, the really minor extent in which this is true is not generally understood and should therefore be made plain; and as the spread of winter diseases, such as pneumonia and "colds," may be influenced by such factors, especially those concerned with ventilation, a short consideration thereof will be of interest now.

The actual oxygen content of air in our cities varies little from the normal, under ordinary circumstances, outside or within our closed houses; and even should there be a marked difference in this particular between city and country air, an increased rate of respiration, as takes place when we ascend to any considerable elevation, would make up the deficit without appreciable harm to our health, as is plainly shown by the well known salubriousness of mountain resorts. But what we have particularly to guard against are the impurities added to the air by our commercial and personal activities.

Our factories, through their furnaces, add many gaseous compounds of sulphur and carbon, and sometimes of nitrogen, that are poisonous to the blood if inhaled, rendering it incapable of carrying the normal amount of oxygen and probably also directly damaging the various tissues. Similar gases escape from sewers, putrefying refuse, and house fires, and our bodies even add their quota. Such effluvia, when escaping exteriorly, are usually so diluted, washed out of the air by the rain, or driven away by the wind, that as air contaminants they are then of negligible importance.

The effect of a varying amount of water-vapor contained in air may be noted here, and I will call attention first to the action of an atmosphere completely saturated with it. This prevents any evaporation from the body's surface and so arrests a principal method of heat dissipation, as water in passing into vapor absorbs and carries off much. The particular oppressiveness of a sultry day is due to this restriction combined with the interference of the damp air with good ventilation through its blanketing action on air currents and diffusion.

With an air only partially saturated considerable heat may be borne without discomfort, as evaporation of perspiration goes readily on, carrying off the excess. The Turkish bath furnishes a familiar example and an experimenter once exposed himself for a few moments in an oven in which meat was roasting, without injury or elevation of body temperature. As the temperature of air rises, its capacity for water greatly increases, and while it readily obtains the latter out of doors, within it may, by artificial heat and lack of water supply, become very dry and irritating to the air passages, as in becoming saturated on its way to the lungs it absorbs more water than the upper respiratory tract is normally able to supply and leaves a trail of dust behind which the lining cells are unable to dispose of, not being able to spare the mucus necessary to entangle and carry it off.

For this reason all stoves and furnaces should have attached to them a small vessel containing water which the heat will vaporize, and from the valve of every steam radiator a small jet of steam should be given egress.

Street air is rarely harmfully polluted except by dust; although in narrow lanes and airshafts, especially when air currents are absent and the humidity is high, gaseous waste matters may accumulate considerably, as previously explained, depending directly upon the neighborhood state as regards coal consumption, gases from special factories and the presence of putrefying materials such as garbage, manure, etc. It is, however, principally within the closed rooms of homes, offices, and factories that injurious gases, together with many other unclassified exhalations, accumulate in dangerous quantities.

The factors which directly control the indoor-air content of these various harmful substances are the heating, lighting, and cooking arrangements; the number of individuals per given air space, their general cleanliness in person and habit; and the construction and ventilation of premises.

Steam-heat and hot-water-heat neither add to nor take from the composition of the air, and their sole effect is to produce its expansion, thus increasing its capacity for moisture. Coal stoves, especially Baltimore heaters and hot air furnaces, on the other hand, always add an appreciable amount of harmful gases, especially when draughts are closed, and in providing adequate ventilation allowance must be made therefor, although the great influx of outside air brought by the hot-air furnace and the consequent hastening of the outflow from a room counterbalance to a large extent the ordinary pollution from this form of heater. In heating the ovens of kitchen stoves there is always a partial obstruction of the draught, and with the many openings around the lids and joints, this gives ample opportunity for the escape of gases. Cooking stoves with ventilated hoods catch most of the gases and carry them off. Unfortunately, many persons cannot afford to live in apartments whose kitchens, thus far, are so equipped. In the use of coal stoves and hot-air heaters, both for cooking and house warming, one cardinal principle should always be observed and that is never to put coal on the fire while any draught is turned off, and to keep the same turned on for at least a few minutes after adding a new supply until this has become quite hot, in order to prevent the escape into the house of the great amount of gas which is driven off from the coal when first added. This excess of escaping gas

has usually subsided by the time the topmost pieces of coal have become too hot to be handled, although at no time should a draught be allowed to remain closed while a noticeable amount of gas escapes into the room.

The ordinary kerosene lamp of sixteen candle power uses as much air as seven persons, the common (bat-wing) gas burner, of equal illuminating strength, as much as five, while this same flow of gas, if burned with an incandescent mantle, demands no more air but gives a light nearly five times as brilliant. An electric-bulb light has no effect upon the surrounding air.

Gas and oil used for heating have of course an effect similar to the same when burned for light, the sole difference, varying with the quantity used, being one of degree. The product of this gas or oil combustion is only carbon dioxide and water vapor and, in the case of gas, traces of sulphur compounds, unless, through fault of apparatus or material, some of the gas or volatilized oil escapes unburned.

The air we exhale contains about four per cent. less oxygen than when it was inhaled and in its place we find the gas carbon dioxide, derived principally from the oxidation of the starches and sugars of our food. This gas, always produced when coal, wood, or any carbon-containing material is burned, is so rapidly absorbed by all plant life, its carbon part being stored up and its contained oxygen given back to the air, that it never exceeds 6/100 of 1 per cent. of the outside air, even in our city streets. Within our dwellings, however, it accumulates rapidly, and when it has reached a percentage about double its limit in the outside air, a sensation of oppression may be distinctly felt, especially by one entering from outside. Recent investigators claim, however, that this sensation is entirely due to interference with the body's heat-regulating mechanism by the increased temperature and moisture saturation of the air and that if it be kept in motion, thus counterbalancing its lessened ability to take up perspiration through bringing more air in contact with the skin in a given time, many times this carbon dioxide percentage can be tolerated without either discomfort or apparent harm; still, since the general effect of impure air as a whole is known to be positively and uniformly injurious, and as there is no reason to economize it, nothing short of as perfect ventilation as may be secured under modern housing conditions should be tolerated.

Our respiratory system, besides serving to admit oxygen, has important excretory duties, the outflowing air carrying away waste matter, including carbon dioxide and putrefiable organic matter, greater in amount and no more fit to be taken into the body again than that thrown off by the kidneys. This waste and the emanations from the body, varying greatly with the persons present, are the most harmful contaminations of the air we breathe. Their reintroduction over and over again compels the system repeatedly to cast out that which should have been rid of in one effort, besides, their greater concentration must intensify all poisonous effects. The result of the accumulation of waste products, as affecting living cells, can readily be observed in connection with bacteria whose growth is at first slowed, and finally the organisms are forced into a resting stage or even destroyed, although ample food supply may be available. The aforementioned emanations, which go under the general name of "crowd poison," are recognized by their odor only and little definite is known concerning their chemical composition, but besides putrefactive gases they are probably largely made up of suspended solid particles. They are added to the air from the breath, decomposing perspiration, and intestinal gases of individuals and, when inhaled, probably tend to poison the body much as intestinal putrefaction ("auto-intoxication") does.

Air leaving the lungs contains no suspended material, but that entering is far from being its counterpart, as it is loaded with everything making up that most complex mixture called dust. In the country, any that may be present, aside from a slight amount of powdered soil, consists of the pollen of various plants, while in town it is hard to say what does not form a part of it. To start the reader's thought, a few components may be mentioned as pulverized stone, coal, iron, ashes, soot, manure, woolen and cotton fibers, leather, powdered substances from special factories, various animal and vegetable matters from waste food and all the microorganisms that flourish thereon, to which is added dried sputum, containing the germs of tuberculosis, pneumonia, "colds," and possibly many other transmissible diseases. Our streets are filled with this accumulating mixture which settles down time and again, only to be disturbed by breeze, passing vehicle, or street sweeper, until finally it is blown away or washed from air and street by a rain storm. If one successfully dodges an ash can or a street sweeper and walks upon the leeward side of the way, sure fate corrals him in the street car, which acts somewhat as a refrigerator for these delicacies and keeps them constantly on the jump as may be seen in the glancing ray of sunlight down whose golden path, to the imaginative, fleets of Zeppelins and aeroplanes manned with all the microbes of bacteriology seem to pour.

Dust particles, of course, in a degree directly dependent upon their composition, affect the surface of the respiratory tract (nose, throat, bronchial tubes, and lungs) and, as with a charge from a shot-gun, each pellet works its woe, although the general result depends largely upon the number and nature of those reaching the mark.

It is, however, particularly in connection with its association with the germs of disease that dust is dangerous to the general public, and although some regard each speck seen afloat as a harbinger of such passengers, the distribution of living disease-producing elements is much less general and, although tubercule bacilli, and a few other highly resistant pathogenic organisms, may live several days after drying, if protected from direct sunlight, most disease-producing microbes die within a few hours after such exposure. In rooms, however, in which a sufferer from disease, or any carrier, in nose, mouth, or throat, of specific germs, even though not the subject of active disease, coughs, sneezes, and expectorates, the dust is usually infectious, since a supply of the germs is constantly at hand to substitute those dying as a result of extreme drying and exposure to light; and some even float in a moist or partially dried state. Even though the specific germ may not always accompany the dust, the latter, through mechanical irritation, destroys the protective cells lining the respiratory tract and renders subsequent invasion an easier task. Stone cutters not specially protected exemplify this, as it is said that 95 per cent. of all illness among them is due to lung tuberculosis.

The screening of air is greatest when inhaled through the nose (mouth breathing giving little protection to the lungs) where it is warmed, saturated with moisture, and most of its floating particles caught, the remainder of course being deposited lower down in the bronchial tubes and lungs. The latter are able, without injury to themselves, to dispose of a small quantity—about that which usually reaches those of a country resident—but, as is well known, in our cities the lungs of all constant inhabitants become colored gray by the deposited dust.

All common "colds," so-called, are due to an infectious process produced by a rapid extension of growth of microbes already present, permitted through a lowering of the body's special resistance, or through contagion, either direct or through the medium of dust, and the general belief attributing their causation to cold air or a draught is both fallacious and unfortunate, as thus the exclusion of fresh air and the inhalation of its foul debilitating dust and germ-laden substitute is encouraged.

The coincidence of cold weather and frequent "colds" is chiefly responsible for their association in the popular mind as cause and effect, although, of course, actual chilling may, through its debilitating influence, predispose. Furthermore, efforts to keep warm often lead to the use of impure and irritating air. The above mentioned belief has been strengthened by the direct irritating effect of cold air upon the already inflamed lining of the air passages and its action, through contraction of the surface blood-vessels, in temporarily congesting those within, with consequent embarrassment of respiration. In cold weather it is extremely difficult to secure good ventilation owing to the discomfort that people fear will result, and this is the factor, more even than faulty construction, responsible for the vile air which so many of us breathe in the winter time. It is notorious that farmers during the cold months, although situated in the midst of an ocean of fresh air, are among those whose health suffers most from such effects, brought about through the common practice of stuffing cracks and hugging the stove. In the city, it is not alone the tenement that requires ventilation, as frequently the houses of the rich, the workrooms of factories, and the closed cars on our streets are as tightly shut off from outside air as their construction will permit.

Overcrowding as an air-contaminating factor is certainly patent, since it is so frequently accompanied by general uncleanliness and poor ventilation in premises often so arranged as to make thorough aeration difficult of accomplishment, besides the multiplication of individual contaminating factors proportional to the number present.

There are no hard and fast rules by which the public may be guided in the question of ventilation although, through an understanding of the principles just recounted, with the reminder which the nose unfailingly gives upon first entering a badly ventilated room, the question would be practically covered. So let the windows be opened, a little top and bottom, to permit an in and an out current, and, if necessary, let more clothes be worn, but do not permit the respiration of the foul air so common indoors in winter, and much will be done to reduce possible danger from pneumonia as well as from many other maladies.

Overcrowding should be avoided when possible, but when not, special provision must be made to meet the unusual requirements, and it should be noted that nothing short of an actual air draught through premises so occupied can be thoroughly effective.

While no inside room can be kept in a state of perfect ventilation, so long as our building practices allow their construction, we will have to make the best of the situation and do our utmost to overcome the difficulties. One step in the direction of entirely forbidding additions to the number of such rooms is the requirement which has recently been enforced by the Tenement House Department that all inside rooms must have at least one window opening through to an outside room, and, although the good which might result is much reduced through the common practice of allowing such windows to remain closed, the fact that an entering wedge has been driven is promising.

Dust in our streets might be controlled by the regular sprinkling of all unpaved surfaces and by requiring the street-sweeper to make thorough use of the watering-can before applying his broom. The new system of street flushing, introduced in some of the larger cities with a plentiful water supply, is ideal, and if carried out efficiently will do great good.

In our houses, even a greater reform has to be wrought, the feather duster and broom will have to be discarded and the damp cloth substituted. While carpets remain in vogue, of course, some sort of dust disturber will have to be used, but wet tea leaves, wet saw dust, or wet newspaper scraps will catch a good deal and prevent it from being driven from place to place, when, at each flight, it has an opportunity of entering our air passages. Vacuum cleaners are, of course, effective in this line. Some day, when sanitary science is more of a practice and less of a theory, our buildings will cease to be the dust-traps and microbe screeners that they now are, and their inmates will lose their belief in the greatest show for the least money, and will succeed to homes that combine cleanliness, comfort, and beauty in perfection. Then perhaps the Mohammedan's practice of removing his shoes before entering a mosque might be applied and all street dirt left beyond the baby's reach. Every effort will be made to secure a supply of Nature's best air and there will be no room without provision for its constant renewal. It has been calculated that a proportion of one-half the outdoor maximum amount of carbon dioxide (3/100 of 1%) is a safe limit necessitating a room space of 1,000 cubic feet, one large hall room's capacity, for each person, with ventilation sufficient to change all the air at least three times an hour. The openings necessary to accomplish this vary with the relative temperature within and without, upon which exchange currents depend, as the more heated air is the more it expands, consequently growing lighter and making the same efforts to rise above its cooler and therefore heavier surroundings as oil does when water is poured upon it, it issues from a heated room through every aperture with a velocity proportioned to this difference in temperature, the cooler and heavier air flowing in to take its place, and this in turn is warmed and follows the preceding. From this we may deduce that a room artificially heated in winter requires a smaller outlet than one not warmed and that the greater the heat of its contained air the more rapidly will it be renewed through the windows and crevices.

It is this property of air that makes it desirable

to place heaters near the lowermost openings of a room where they can warm the incoming air, and to have outlets near the ceiling toward which all currents tend, including especially the air vitiated by the body, thus keeping up a constant stream which washes all impurities from the room as soon as formed.

The most reliable and practical test of the salubrity of an apartment's atmosphere is the presence or absence of that sensation of oppression to a newcomer already alluded to, who, by the way, must not have had his sensibilities blunted by prolonged residence in those hybernating retreats of the sickly so common in our cities, nor have delighted in the sticky atmosphere of the winter street car where often even grease seems to float and microorganisms revel.

But even when this test is favorable, should the season or the heat available permit an open window, it should always be had, as only in the open where the purifying forces of nature have full sway can the best air be obtained, and as we are none too healthy this should always be sought. The well known difference between the general healthfulness of indoor and outdoor life is due largely to the variance in quality of this air-food, a prime factor in determining the thousands of cases of consumption with which our cities are afflicted. Not alone has the outdoor treatment been successful with tuberculosis, but many other maladies have been found to be profoundly affected by free air. A physician of international reputation even goes so far as to state that a tramp suffering from pneumonia by the roadside has a better chance to recover than a millionaire in a closed room.

From the foregoing we readily see that impure air may influence the general health in so many little ways, over such long periods, that the sum total often makes all the difference between disease and health. Certainly the respiration of the gases and compounds mentioned renders the body less able to perform its normal functions and an easier prey to the disease germ which it cannot but frequently encounter amid just those conditions where the air is usually most foul.

In concluding the subject, the importance of a continual supply of fresh air to our lungs, even more necessary to the sick than to the well, should be emphasized and the public reminded that its lack is a contributing cause to many cases of illness, some of which could never occur without its aid. Of all the conditions of civilized life depreciatory of vigorous health this is the most widespread in its influence and the least recognized by the public, not one in a hundred of whom does not suffer from its effects.

140 Clinton Street.

THE PHYSICIAN'S INTERESTS IN THE WORKMEN'S COMPENSATION LAW.*

By HENRY S. STARK, A.M., M.D.,

NEW YORK.

The officers of the Society are to be congratulated in having assigned the greater part of an evening to the discussion of a question of such vast economical interest to the profession. If the County Medical Society would adopt this practice generally, and would utilize all its vast resources for the benefit of its members, there would be no necessity for the formation throughout the city of physicians' benefit societies and physicians' economic leagues. It is just and proper at our meetings that we should occasionally turn from the strictly scientific to the human side of the practise of medicine. The Workmen's Compensation Law, like many other laws passed by the Legislature, as for instance the Boylan habit-forming drug bill, are notorious examples of what might be styled rapid transit legislation, bills that are railroaded through the Legislature in an unprepared and unfinished state, with the result that they are riddled by amendments by the next legislature so profusely that the original is scarcely recognized. In the case of the Workmen's Compensation Law, no hearing was ever given to any medical society or to any representatives of the profession at large, a most unusual procedure which should call for severe criticism. The medical profession has always received scant recognition from the public or from legislatures, state or national. The practice of medicine has never been considered a hazardous occupation, the sacrifices that physicians daily make in their practice, go unrecognized by state or nation or public at large; the too often gratuitous services are lost sight of in the aggregate; who ever heard of a hospital physician or professor in a medical college being pensioned? In these days of pensioning by such well-known foundations as Carnegie, Rockefeller, and Sage, a professor of homiletics who never handles an instrument more dangerous than a toothbrush or a fountain pen, is assured of a pension in the twilight of his professional career, likewise the professor of Egyptology and of descriptive geometry; but a professor of surgery who risks his limb and his life daily in the operating-room or the professor of bacteriology or pathology who risks his life and limb daily in the laboratory and autopsy-room are not considered worthy of a pension after years of sacrificial service. A physician is a distinct asset to a community, the medical profession itself is a constructive resource to the nation. In the present European struggle we can dispense with the artist, the poet, the literateur, but with the doctor we never could. I mention these instances to give color to the fact that physicians' services are not generally acknowledged as they should be and the Workmen's Compensation Law is no exception to the rule.

In the *New York State Journal of Medicine* for November, 1914, the statement is made that "The profession has every reason to be grateful, as it is the first time that our legislative body has recognized the rights of medical men, etc." Let us pause here a moment and see how true this is. It is also claimed that in many instances injured laborers were ambulanced to hospitals and that for such cases neither doctor nor hospital derived any revenue, while under the present régime physicians and hospitals do get a fee from such cases. Now let us see what the customary practice really was before we had a compensation law. The usual custom was that the injured workman would pay a regular fee for first aid and subsequent services. The laborer, like all other provident employees, usually had money laid aside for such a contingency as injury or sickness; in other instances he was a member of a benevolent society which allowed weekly benefits during disability from sickness; in still other instances, and this very often happened, the employer or company would pay for surgical services ren-

*Remarks made in the discussion on the Workmen's Compensation Commission at the February meeting of the County Medical Society.

dered an injured employee. It is true that under the present law patients sent to hospitals are expected to pay the hospital and physician, but let me ask how many of you are visiting surgeons to hospitals? Are not the hospital doors closed to most of you, and this last feature shows the injustice of our present hospital management, namely, that the doors of the operating-room and wards are closed to the profession at large. I firmly believe that all hospitals should be open to all physicians in good and regular standing, and not be given over entirely to the visiting staff. That is the next economic question the doctors in this city should take up. In consideration of injured workmen being taken to the hospital, many firms, companies, and corporations made yearly donations to such institutions. Now I imagine such donations will cease, and thus the hospitals will not be the gainers to the degree that they believe they were.

As a practitioner it has fallen to my lot to treat many injured workmen, and in almost all instances these patients paid me cheerfully for services rendered. Personally I am not opposed to taking a fee lower than the services are worth, but I decidedly object to being compelled to do so by legislation or by insurance companies. The medical and surgical fee bill which puts one in mind of the scale of prices, posted in the boxoffice of a theatre, is in my humble opinion the first step towards commercializing and socializing, if you will, the medical profession, a spirit which we as physicians have always resented and which we denounce today as being inconsistent with our Hippocratic oaths. We demur at the attempt of the State to barter for our service as though it were a piece of merchandise or a real estate parcel. Our services cannot be estimated arbitrarily in dollars and cents, each physician's service is a law unto itself; but once the State attempts to put an official value on medical services, it is morally, legally, and economically bound to put an honest and current appraisal on such services and not a rock bottom, prohibitive, and unjust appraisal. It must be evident to those who are familiar with this new act of the legislature that the interest of the insurance carriers came in for more consideration than did the interest of physicians. I would like to call your attention at this time to the methods and procedures which led to the adoption of this medical and surgical fee bill.

Many physicians are under the impression that this fee bill is a bill that has been passed by the State legislature; now as a matter of fact it is nothing of the kind. It is a scale of prices temporarily adopted by certain representatives of the Workmen's Compensation Commission, together with five members of a special committee of the Medical Society of the State of New York. Now my claim is that this latter committee was never clothed with authority from the State Society to enter into any such contract with the Commission. According to the resolution which was adopted by the House of Delegates of the State Medical Society in April, 1914, this committee was charged with the sole duty of presenting the views of the profession on questions that might come up for the solution affecting medical men to the compensation committee and nothing else. The committee was not authorized to fix a scale of prices with the commission; its duty was first to report back to the House of Delegates which created it. Now inasmuch as the next meeting of this body will not take place until April, 1915, in Buffalo, the report of this committee can not be handed in and acted upon until then. Section 6, Chapter III of the by-laws of the State Medical Society of the State of New York specifically states that special committees shall report back to the House of Delegates. On the other hand, as far as the compensation committee is concerned, it may be argued that it had no warranty in law or in fact to fix on a scale of prices with this special committee for the reason that the latter did not represent the profession at large but only the State Medical Society. The State Medical Society does not represent even half of the medical profession of the entire State. The other half was never consulted. A legal construction of these facts would seem to indicate that the medical and surgical fee bill is not binding upon any member of the profession and that it is no legal contract and therefore physicians have the right to set their own price on the value of their services as though there were no Workmen's Compensation Law in existence.

I think it would have been the part of wisdom if the Compensation Commission had consulted the medical profession of the State of New York and not solely the Medical Society of the State of New York. Unfortunately the medical profession of our State is not a perfectly organized body.

I would suggest to this commission, if it were desirous of getting the views of the physicians of this State as to what a proper surgical fee is, that it circularize every physician in the State of New York to that effect. This procedure would readily bring to light the majority opinion of physicians throughout the State and would furnish a rational working basis to be used in appraising surgical and medical services. Under the present operation of the law the individual rating and standing of the physicians in the community is not recognized, neither is the time consumed in attendance nor the character of the service, considered. All these elements should have received careful attention before a flat rate applicable in all instances was adopted. It must come to this before we will allow ourselves to become reconciled to the new law. We do not object to the new law. We recognize it has come to stay, but we want fair treatment from those who are empowered to regulate and prescribe fees for services rendered.

Let me at this time call your attention to a matter which transcends in importance the question of a fee bill, and it is this: has the State really the constitutional right to say what a physician may charge for his services and limit such fees to a certain scale?* While I am in nowise in a position to offer a legal construction of the State's rights to regulate physicians' fees, I venture the prediction that if the matter were brought up for adjudication in the courts the legality of the State's act would not be sustained. This society in the November meeting decided by resolution to repudiate the medical and surgical fee and to instruct its delegates to introduce and support a resolution to this effect in the House of Delegates of the State Medical Society in April. This measure seems to me to be wise, just, and fair, and we should stand by it until measures are taken by the Workmen's Compensation Law looking to a fair reconciliation of our individual differences and to a more just standardization of fees.

1309 Madison Avenue.

*I am now referring to physicians who are of course not in the employ of the State or any of its agencies. That applies to most practitioners in the State.

PERMANENT ENLARGEMENT OF THE CONTRACTED PELVIC OUTLET.*

PRELIMINARY REPORT

By FRANKLIN D. SMITH, M.D.,
CHICAGO, ILL.

MANY cases of dystocia due to contraction of the pelvis can be temporarily overcome by a limited increase in the diameter of the pelvic outlet. Many borderline cases could be permanently relieved by an increase of not more than 1.5 to 2 centimeters in the conjugate diameter. It is possible to obtain this result by permanently spreading the pubic bones. This can be accomplished by the isoplastic transplantation of bone of a certain width to maintain the desired distance between the pubic bones.

The pubic bones are separated at the symphysis by a fibrocartilagenous articulation, called the interpudic disk. Each bony surface is covered by a layer of hyaline cartilage varying in thickness in different individuals. The bony surfaces are very irregular, presenting many nipple-like projections, which aid in securely fastening the hyaline cartilage to its surface. These hyaline plates of cartilage are distinctly separated from the compact bone, but bone gradually merges into cartilage, resembling very much the structure at the epiphysis of any long bone with the exception that the space of transition is very narrow in the symphysis. Between both plates of opposing cartilage is found an intermediate stratum of fibrous tissue. In this fibrous tissue structure is found a cavity, not lined by synovial membrane, called the cavum articulare, which can be demonstrated after the tenth year of life by a vertical section through the symphysis.

The structure of the pubic bones in this region is both compact and cancellous bone. A very thin layer of compact bone is found beneath the hyaline cartilage, although in the nipple-like projections the compact bone is thicker than in the depressions. Underlying the compact bone is found a very vascular, spongy, cancellous bone.

The transplant is obtained from the internal surface of the tibia near its upper extremity. In this region a transplant of sufficient width and length can be obtained. The periosteum can be removed with the transplant and may serve a much disputed purpose. The transplant must be obtained fresh and unless it retains sufficient vitality to proliferate and regenerate the results will not be satisfactory.

An incision is made over the symphysis long enough to accomplish the technical details and at the same time to conserve the tissues in this region, giving special attention to hemostasis and sepsis. The dissection is carried down to the symphysis and the interpudic fibrocartilaginous tissue is completely removed, curetting the irregular nipple-like projections of bone on the surface. The bones are separated a certain distance by an instrument made for the purpose, as previously determined, and the transplant is set in place. The transplant may be held in place either by grooves made in the pubic bones or by a heavy kangaroo tendon bound about the graft and pubic bones. After closing the incision with catgut a properly fitting plaster cast is applied. The progress and position of the transplant can be ascertained at varying intervals of time by means of the Roentgen rays.

UNIVERSITY HOSPITAL.

Medicolegal Notes.

Administering Anesthetic—Intent to Procure Abortion.—In criminal proceedings for administering a drug with the intention of procuring an abortion in violation of secton 12,412, Ohio General Code, the Supreme Court of that State made the following rulings: Whoever, with the intent to procure the miscarriage of a woman by the use of an instrument or other means, administers to her a nonabortive drug as an anesthetic preparatory to the use of such instruments or other means of procuring an abortion, and the woman dies in consequence of the administering of such drug before the use of instruments or other means by such person to procure a miscarriage, and it does not appear that such contemplated miscarriage is necessary to preserve her life, or that the procuring of such miscarriage was advised by two physicians to be necessary for that purpose, is guilty of a violation of the provisions of the statute. Under such circumstances every act done in furtherance of such unlawful purpose is an integral part of the whole unlawful transaction; and the fact that death ensues before the final act in the contemplated crime can be accomplished is not a defense to an indictment charging a violation of the statute. But if it appear that a nonabortive drug is administered to a woman as an anesthetic to enable a duly authorized and practicing physician fully and carefully to examine into the woman's actual condition for the purpose of determining if it be necessary to procure a miscarriage in order to save her life, and the woman die from the effect of the drug so administered, and no miscarriage is performed, nor intended to be performed unless the examination disclose that it is necessary to preserve the woman's life, no offense has been committed within the provisions of the statute. Evidence tending to show that no secrecy is maintained in the transaction; that a second physician is called in to administer the anesthetic; that while the woman is in a state of anesthesia the attending physician makes an examination for the purpose of determining whether the fetus is alive or dead, and upon such examination does determine that the fetus is still alive, and that it is not necessary to procure a miscarriage in order to preserve the woman's life, and, having so determined, makes no use of any instrument or other means to procure a miscarriage, but immediately desists from further efforts in that direction, and directs that the woman be restored to consciousness, is proper evidence to be admitted for the purpose of showing the absence of criminal intent in administering the anesthetic.—State v. Tippie, Ohio Supreme Court, 105 N. E. 75.

Basis of Expert Testimony.—Testimony of a physician, so far as it is expert testimony, may be based upon personal examination, or upon the facts proved upon a trial, or upon both such examination and proven facts, or, preferably, it may be based upon hypothetical questions.—George vs. Shannon, Kansas Supreme Court, 142 Pac. 967.

Practising Medicine without License — Manipulation of Nerves, Bones, and Tissues.—In proceedings for practicing medicine in the State of Nebraska without a license it was held that to "operate on, profess to heal or prescribe for, or otherwise treat any physical or mental ailment of another" is "practising medicine" by the express provision of section 2724, Nebraska Rev. St., 1913. It is held to be unlawful in the State of Nebraska to treat professionally and attempt to heal another by manipulation and adjustment of nerves, bones, and tissues of the body, without first obtaining a certificate or license from the state board of health, as provided in articles 2 and 8, ch. 27, Rev. St., 1913. Every such treatment constitutes a separate offense, although of the same individual and for the same physical or mental ailment, if such treatments are on different days and entirely independent of each other.—Harvey v. State, Nebraska Supreme Court, 148 N. W. 924.

Privileged Communications.—In an action for injuries to a passenger by falling on a defective station platform, it is held that a physician who had attended her was rendered incompetent by the Arkansas statute forbidding a physician to disclose any information acquired from a patient while attending him in a professional capacity, and which information was necessary to enable him to prescribe as a physician, to testify that the passenger was afflicted with cancer and died of that disease.—St. Louis I. M. & S. Ry. Co. v. Fuqua, Arkansas Supreme Court, 169 S. W. 786.

TUBERCULOSIS AND GOUT.

THE association of arthritic manifestations with pulmonary lesions has been known for a long time. The subperiosteal deposition of new bone, particularly marked in the region of the wrist and ankle and frequently observed in cases of bronchiectasis, has given rise to the clinical conception of pulmonary osteoarthropathy. In 1889 Sir Andrew Clark described an "arthritic hemoptysis" occurring in elderly persons and attributed to arthritic changes in the capillaries of the lung. It is widely recognized that a distinct antagonism exists between tuberculosis and the arthritic diathesis. In 1869 Maurice Raynaud noted that tuberculosis developing in a gouty individual is limited to the apex of the lung, and runs a slow and almost latent course. G. V. N. Dearborn in the article on "Diathesis" in the "Reference Handbook of the Medical Sciences," Third Edition, 1914, quotes a memoir by Sarda and Vires, in which there are pointed out the rarity of pulmonary tuberculosis in the arthritic, the resistance of the tissues of the arthritic to the invasion of the tubercle bacillus, and the certain arrest of the disease when such invasion does occur.

The mutual influence of tuberculosis and gout is discussed in an interesting article by Arthur Mayer in the *Zeitschrift für Tuberkulose*, December, 1914. He has already delineated a typical form of gout in which the sole manifestations occur in the respiratory organs, and to which he has given the name "pulmonary gout." The disturbance in purin metabolism which was characteristic of these cases suggested a new line of investigation, namely, the character of the purin metabolism in frank cases of pulmonary tuberculosis. Reference is made to the observation by Bandelier and Roepke that in persons with a disturbed purin metabolism tuberculosis runs a particularly benign course, and shows a striking tendency to fibrosis. The long recognized antagonism between tuberculosis and gout is, however, not an absolute one and must be accepted with two important reservations, namely: (1) The antagonism applies only to constitutional gout, for gout the result of lead poisoning tends to favor the development of tuberculosis. (2) There are also cases of atypical gout which may exist in association with tuberculosis to an extent far greater than is generally recognized.

Mayer reports a series of such cases which he has carefully studied. The outstanding feature in the clinical history was the occurrence of pulmonary hemorrhage as an apparent equivalent of an attack of gout. Hemoptysis occurred following an injection of tuberculin and coincident with the maximum of uricacidemia. Just as in cases of typical gout, there occurred, preceding the pulmonary hemorrhage, a fall in the uric acid content of the blood, which content rose very high during and after the hemorrhage. The curve of the excretion of glycocoll likewise behaved exactly as in cases of gout, namely, the reverse of the uric acid curve.

The conclusion is reached that in some cases of gout the sole clinical manifestation is pulmonary hemorrhage. It cannot be maintained that this hemorrhage is the result of the wounding of the minute pulmonary capillaries by uric acid crystals deposited in them, for it has been proved that the lungs, and particularly tuberculous lungs, have a very slight affinity for uric acid, nor have uric acid crystals ever been isolated from lung tissue.

SPLENECTOMY IN PRIMARY PERNICIOUS ANEMIA.

THE first splenectomy for primary pernicious anemia was done at Eppinger's suggestion in March, 1913. Five German cases had been reported up to the time when Harpole and Fox (*Surgery, Gynecology, and Obstetrics*, February, 1914) reported the first case treated by splenectomy in this country. Their operation was done of their own initiative and without being aware of the fact that these German cases had been reported between August, 1913, and the date of their operation. Their reasons for operating were that the patient was going from bad to worse under medical treatment and the fact that there was a palpable spleen which could not be accounted for by a previous malaria or other disease. Operation was followed by marked improvement in the patient's condition. Next, Roblee, writing in the same journal in November of last year, reported having treated two such cases by splenectomy. In the first case the result was astonishingly good almost from the outset; a second operation about six weeks later, for the liberation of colonic adhesions, was well borne and the patient was constantly gaining at the time the article was written. The second patient showed some improvement, but the prognosis was not considered so hopeful as in the case of the first patient operated upon.

From these and the few other reported cases, Roblee believed himself justified in claiming that splenectomy in primary pernicious anemia does not present any very unusual difficulties and the operation, unless a former splenitis has been present with resultant adhesions, does not cause much shock or inconvenience to the patient. The improvement is immediate and striking and a comfortable temporary lease of life appears to be assured, although, in view of the variability of conditions in cases suffering from this disease, we are not warranted in promising a permanent cure. Finally the immediate results are far more pronounced than those following a palliative operation for cancer or other chronic conditions, and if such an operation is

ever justifiable, this operation certainly is indicated.

This report was so encouraging that we were about to call attention to the new resource in the treatment of these otherwise hopeless cases when Roblee published a second communication (*Jour. A.M.A.*, March 6, 1915) in which he discussed the causation of this type of anemia, the normal function of the spleen, the immediate effects of splenectomy, and the later clinical results. He has found 40 cases recorded in which operation has been performed up to the present time, and in this article he gives a rather complete résumé of the subject. As to the results, he says that he has been unable to find a record of any case that the surgeon has been willing to report as cured. There has been an immediate and striking improvement in the majority of cases, but this improvement seems to last but a few weeks or months and in none has the blood picture become absolutely normal. His first case, which appeared so promising in September, ended fatally in December. The second, which did not appear to justify so favorable a prognosis shortly after operation as the other, gradually improved up to the time it was lost sight of in October. Roblee believes that blood transfusion should be resorted to in all cases before operation and insists that other therapeutic measures should be combined with splenectomy.

It may be that here lies the solution of the problem. Operation has added months to the lives of a majority of the patients, and it is to be hoped that the opportunity for study under the changed conditions brought about by the removal of the spleen will ultimately result in the discovery of the toxin or other cause of perverted function at the bottom of these cases and suggest the proper therapeutic attack. Meanwhile, since these cases are otherwise hopeless, splenectomy is certainly indicated, and it should be regarded as a duty by each operator to avail himself of the cooperation of a skilled pathologist and internist in the subsequent study of the case and to report results in every instance.

CLINICAL PROBLEMS IN DIPHTHERIA.

One of the most interesting phases of the study of diphtheria is the percentage of error in its diagnosis. This percentage is a large one in spite of the fact that in addition to the clinical symptoms there are objective evidences of the disease and there is the aid furnished by bacteriological diagnosis. But there are cases that clinically present all the characteristics of diphtheria and nevertheless are not diphtheria, and vice versa. Moreover, bacteriological diagnosis is not infallible. Overlooking the faults in technique and the accidents in the cultivation of bacteria, which account for a definite percentage of error, one may be certain that not all cases of membranous sore throat or follicular tonsillitis in which diphtheria bacilli are present are really cases of diphtheria. These bacilli may be non-virulent and innocent bystanders that have nothing to do with the disease that may be present.

An impressive commentary on the percentage of error in the diagnosis of diphtheria is furnished by the report for 1913 of the Metropolitan Asylums Board Hospitals of London. Of the cases admitted the percentage error was 15.6. There were 1,009 cases wrongly certified as diphtheria; these included 699 cases of tonsillitis, 64 of laryngitis, 23 of rhinitis, and 140 of bronchopneumonia. In an article based on the observation of nearly 3,000 cases of diphtheria, Cabrera *Semana Médica*, 1914, No. XXI) states that in 80 per cent. of his cases the bacteriological and clinical diagnoses were in accord. In other words, in 20 per cent. of the cases either the clinical manifestations or the bacteriological findings alone sufficed for a diagnosis. But the opinion is ventured that the clinical symptoms are even more to be trusted than the bacteriological findings. Opinions may differ as to the relative weight to be given to the clinical and laboratory findings, but in this as in other fields of medicine the physician's own experience will enable him to make an approximately correct valuation of these factors.

The disturbing element in all calculations regarding diphtheria is the diphtheria carrier. It is often difficult to decide whether in any suspected case of diphtheria one is dealing with an actual instance of this disease or with a disease simulating diphtheria in a diphtheria carrier. Of paramount importance in this type of case is the necessity of making tests to determine the virulence or non-virulence of the organisms isolated. With this idea in mind W. Buttermilch (*Deutsche medizinische Wochenschrift*, 1914, No. 12) has made a study of the clinical valuation of the types of organism in cases of nasal diphtheria in infants. Of extreme importance is the ability to differentiate the virulent types of diphtheria bacilli from the non-virulent types and from the diphtheroid organisms, a matter, however, of great difficulty. The author's study was made on the sixty-five infants in an infant's hospital, among whom there were three cases of genuine nasal diphtheria and two bacillus carriers with virulent organisms and five with non-virulent and diphtheroid organisms. These cases were isolated from one another and further bacteriological study could not reveal any transformation of the non-virulent organisms into the virulent ones, and vice versa. Nevertheless, there is ample clinical evidence that such transformation does sometimes occur.

It is an almost universal practice in children's hospitals to take cultures from the throat and nose of all patients admitted, and if diphtheria bacilli are detected in any patient to transfer the latter to an isolation hospital, even though the patient may have none of the clinical manifestations of diphtheria and the bacilli isolated may be non-virulent. There are many of these patients in public isolation hospitals known as "culture cases"; they usually remain for a long time with no apparent benefit to themselves and frequently to their own detriment. The rational procedure would be for all institutions to take care of their own "culture cases" if the bacilli are non-virulent. These patients should not be subjected to the real danger of superadded infection in an isolation hospital.

HEALTH EDUCATION, NOT COERCION.

THE first annual report of the New York State Public Health Council emphasizes the "new idea" in public health work—leadership rather than coercion. The report covers the council's activities since its creation in 1913 by the enactment of a new public health law. It goes without saying that leadership in order to be effective must be efficient and conducted along the right lines and in the proper spirit. It is also evident that the State is fortunate in this direction in having as its leader the present Commissioner of Health with an able band of coadjutors in the members of the council. The council thus expresses the new idea in leadership in health work: "In the framing of this sanitary code, the council steadily aimed to secure to the citizens of the State all the advantages which science and experience, especially during the last quarter of a century, have offered in the prevention of disease and in the promotion of the common welfare, with the least possible interference with the business, comfort, and convenience of the people concerned."

So far as the sanitary code adopted by the council is concerned, it states that it has attempted to enact a code which would be readily comprehensible to the citizens for whose use and guidance it is framed. In doing this it has eliminated not only useless sanitary procedures and "obsolete quarantine regulations," but has abandoned in its text those technical terms which, although still often used, have lost their earlier meanings and value. Seven chapters of the code have been enacted thus far. The first is entitled "Definitions and General Provisions"; the second relates to "Communicable Diseases"; the third to the "Production and Handling of Milk and Cream"; the fourth regulates the practice of midwives; the fifth relates to "Labor Camps"; the sixth to "Nuisances," and the seventh enacts regulations relating to spitting, the common drinking cup, the common towel, and barber shops.

There is little doubt that hard and fast regulations concerning certain important phases of public health are required not only in New York State but in all States of the country. People are apt to imagine that regulations of the kind constitute a curtailment of liberty, but they do not pause to consider that without such regulations the health of everyone is menaced. If the laws regarding public health are not strictly enforced, disease is afforded an excellent opportunity to originate and spread. It is only necessary to point to the milk supply to show that if the supply is not safeguarded milk, instead of being one of the most important sources of nourishment, is a fruitful medium for spreading disease. The enforcement of the regulations framed by Dr. Biggs and his associates will undoubtedly result in a great improvement in the public health throughout New York State.

THE VALUE OF AUXILIARY CLASSES.

THE methods of education in civilized countries have improved greatly in recent years. It is not so long ago when no special attention was paid to abnormal children and the fact did not appear to be recognized that all children could not be educated successfully on the same lines. At the present time, however, progressive educationalists have come to the conclusion that for the benefit of the community as well as of the individual, mental defectives and other children suffering from afflictions which disqualify them from ever earning a living in the ordinary way, must be so trained that the best use is made of those faculties which they possess. Thus mental defectives, the blind, and the dumb are now all taught to do some work which will not only render them less of a burden to the community but will make their lives happier and more contented. Dr. Helen Macmurchy of Toronto, inspector of Auxiliary Classes for Ontario, has issued recently at the behest of the Legislative Assembly of that Province, a book dealing with the organization and management of auxiliary classes. She has made a close study of the auxiliary class movement in various parts of the world and has put into this little book the result of her experiences, tracing also the history of the movement and the methods in vogue best adapted to minimize as far as is possible the physical and mental defects under which some children labor. The book is well written and arranged and may be termed an excellent text book on the subject. It should prove of great service to those who require information as to the manner in which auxiliary classes should be conducted.

GERMAN GRADUATION THESES DURING THE WAR.

THE titles of the inaugural dissertations for the last semester of 1914 in the University of Bonn (*Muenchener medizinische Wochenschrift*, January 26) show that the war has as yet made no impression on the normal course of medical instruction. Among the subjects represented each by a number of 39 theses, are radiography and radium; psychoses and hysteria; malformations; blood states; tuberculosis; special forms of surgical intervention; appendicitis; disorders of the internal secretions. These subjects are enumerated approximately in accordance with the number of contributions under each head. Some subjects of present vogue are represented by a single thesis only—cancer, syphilis, twilight sleep, etc. There is a natural tendency for the student to embody in his thesis the unusual rather than the trite, whether he reports a rare disease, a peculiar association, perhaps fortuitous, of lesions, a new method of treating a refractory affection, etc. The predominance of theses on radiant energy is due perhaps to its two-fold aspect of diagnosis and treatment. Psychiatry is prominent because of its secondary forensic significance. Worthy of individual mention is a practical dissertation on the treatment of rhizomelic spondylosis with sand baths.

News of the Week.

The Seventh Pan-American Medical Congress will meet in San Francisco, June 17-21, inclusive. It assembles pursuant to invitation of the President of the United States, issued in accordance with an act of Congress approved March 3, 1915. The countries and colonies embraced in the Congress are the Argentine Republic, Bolivia, Brazil, Canada, Colombia, Cuba, Chile, Costa Rica, San Salvador, Ecuador, Guatamala, Honduras, Haiti, Hawaii, Mexico, Martinique, Nicaragua, Panama, Paraguay, Peru, Santo

Domingo, United States, Uruguay, Venezuela, British Guiana, Dutch Guiana, French Guiana, Jamaica, Barbadoes, St. Thomas, and St. Vincent. The organization of the Congress is perfected in these countries and the majority of them have signified their intention to be represented by duly accredited delegates. The Congress will meet in seven sections, viz., (1) Medicine; (2) Surgery; (3) Obstetrics and Gynecology; (4) Anatomy, Physiology, Pathology, and Bacteriology; (5) Tropical Medicine and General Sanitation; (6) Laryngology, Rhinology, and Otology; (7) Medical Literature.

All members of the organized medical profession of the constituent countries are eligible and are invited to become members. The membership fee is $5.00 and entitles the holder to a complete set of the transactions. Advance registrations are solicited and should be sent with membership fee to the Treasurer, Dr. Henry P. Newman, Timken Building, San Diego, California. The Palace Hotel will be headquarters. The President of the Congress is Dr. Charles A. L. Reed, Cincinnati; the Secretary, Dr. Ramon Guiteras, 80 Madison Avenue, New York City.

Committee of American Physicians for the Aid of the Belgian Profession.—The treasurer reports the receipt of the following contributions for the week ending March 27, 1915:

Dr. H. N. Torrey, Detroit, Mich.	$10.00
Faulkner County Medical Society, Conway, Ark.	25.00
Newburyport Medical Club, Newburyport, Mass.	20.00
Lieut.-Col. F. P. Reynolds, M.C., U.S.A., Honolulu, H. T.	25.00
Dr. Waldo Richardson, Seattle, Wash.	5.00
Mrs. O. W. Johnson, Racine, Wis.	5.00
Dr. Joseph Brettauer, New York, N. Y.	25.00
Dr. Lewis Gregory Cole, New York, N. Y.	25.00
Dr. J. N. Hall, Denver, Colo.	5.00
Dr. J. B. Rogers, Independence, Iowa	5.00
Medical Society of the Co. of Westchester, White Plains, N. Y.	25.00
Dr. Alex. Marcy, Jr., Riverton, N. J.	10.00
Dr. S. R. Woodruff, Bayonne, N. J.	5.00
Dr. G. C. McMaster, Pittsburgh, Pa.	5.00
Dr. Charles G. Mixter, Boston, Mass.	10.00
Dr. S. G. Laws, Spartanburg, S. C.	5.00
American Surgeons Clinical Tour of 1914, Galesburg, Ill.	150.75
Colorado Chapter of A. M. P. O. Medical Fraternity, Denver, Colo.	50.00
Boston Society of Psychiatry and Neurology, Boston, Mass.	100.00
Routt County Medical Society, Steamboat Springs, Colo.	10.00
Dr. Bertram M. Bernheim, Baltimore, Md.	10.00
Receipts for week ending March 27th	$530.75
Previously reported receipts	5,221.50
Total receipts	$5,752.25
Previously reported disbursements:	
1,625 standard boxes of food at $2.20	$3,575.00
715 standard boxes of food at $2.30	1,644.50
Disbursements for week ending March 27th:	
230 standard boxes of food at $2.30	529.00
Total disbursements	5,718.50
Balance	$3.75

Medical Work in China.—In addition to the Yale medical work in China, the Rockefeller Foundation has established a bureau to be known as the China Medical Board, the special work of which in the beginning will be to develop a comprehensive scheme of medical education in that country. With a view to building up a body of Chinese men able to teach medical science, the foundation has decided to establish six fellowships, each of $1,000 gold a year and traveling expenses, to enable Chinese graduates to study in medical schools here and in Europe. These six fellows have already been appointed, and one of them is now in this country. The Chinese Medical Board is constituted as follows: John D. Rockefeller, Jr., chairman; Wallace Buttrick, director; Harry Pratt Judson, Frank J. Goodnow, Dr. Simon Flexner, Jerome D. Greene, John R. Mott, Dr. William H. Welch, Wickliffe Rose, Starr J. Murphy, Dr. Francis W. Peabody and Frederick T. Gates. E. C. Sage is secretary of the board, and Roger S. Greene is to be the resident director in Pekin.

Michigan Board of Medical Examiners.—Governor Ferris of Michigan has appointed the following members of the State Board of Registration in Medicine, to serve until September 13, 1919: Drs. A. M. Hume, Owosso; Enos C. Kinsman, Saginaw; Duncan A. Cameron, Alpena; Frederick C. Warnshuis, Grand Rapids, and A. L. Robinson, Allegan.

Clinical Society of the New York Polyclinic.—The regular monthly meeting of the Clinical Society of the New York Polyclinic Medical School and Hospital will be held Monday evening April 5, 1915, at 8.30 P. M. in the Surgical Amphitheater.

General Gorgas Receives the Seaman Medal.—The Louis Livingston Seaman medal for progress and achievement in the promotion of hygiene and the migration of occupational disease has been awarded to Surgeon-General William C. Gorgas.

Removal of the Presbyterian Hospital.—Steps are being taken toward the removal of the Presbyterian Hospital from East Seventieth Street, New York, to a new location on Washington Heights and the trustees of the hospital recently took an option to purchase the former American League baseball grounds, bounded at Broadway and One hundred and sixty-fifth Street. This site is owned by the New York Institute for the Education of the Blind. The property is a large tract containing six city blocks. Part of the site will be used for hospital purposes, but considerable space will be utilized by buildings for special scientific and educational work in connection with the medical department of Columbia University.

Manufacture of Synthetic Drugs in England.—Successful work is reported from various British laboratories in the matter of manufacturing various synthetic drugs which have heretofore come from Germany. This will mean a large degree of independence of Germany in the matter of these supplies after the war.

Course of Lectures and Clinics on Cancer.—The faculty of the Cornell University Medical College announce a course of instruction on cancer for senior students and graduates in medicine, consisting of eighteen lectures to be given at the Medical College, Twenty-eighth Street and First Avenue, at 4 P. M., on Tuesday and Thursday, March 30 to May 27, 1915. Coincident with the lectures there will be a series of clinics in two sections, at the General Memorial Hospital, One hundred and sixth Street and Central Park West, on Mondays and Wednesdays, 9 A. M. to 12 M.

Influenza in Washington.—According to the health reports, grip has prevailed to a greater extent in Washington this year than at any time since 1891. In six weeks the deaths from the disease have numbered 210, as against 113 for the corresponding period last year.

United States Field Hospital Sent to France.—A complete field hospital formerly belonging to the U. S. Army was shipped last week to the American Ambulance Hospital in Paris. The complete unit with its tents, operating tables, cots, medicines, disinfectants, instruments, food supplies, stoves and filters, weighs 16,000 pounds, can be transported on three motor trucks and can care for 108 wounded men at once. Fifteen American automobiles and American doctors and nurses will be detailed to operate it.

For the American Hospital at Paignton.—On the American liner *St. Paul* which sailed for England

last Saturday were Dr. Henry A. Lange of Baltimore and Dr. A. N. Dykes of Atlanta and three Red Cross nurses going to join the medical staff of the American Hospital at Paignton.

Wellesley College Girls have contributed $800 for the purchase of an automobile ambulance for the American Ambulance Hospital.

To Study War Hospital Methods.—Surgeon Archibald M. Fauntleroy, U. S. Navy, has been detailed to make an observation tour of the war hospitals of France, Belgium, and England.

Explaining a Typhoid Epidemic.—Recently several members of the medical and nursing staff of the Sloane Maternity Hospital in New York came down with typhoid fever, and for a long time the origin of the epidemic remained a mystery. Finally a search for carriers among the kitchen staff resulted in the finding of one of the first discovered and best known of all typhoid carriers—in fact the queen of carriers, "Typhoid Mary." This poor woman was first detected as a spreader of typhoid fever by Dr. Soper in 1906, while he was investigating a succession of fever epidemics occurring for four years previously. Soon after that she was taken into custody and held for three years. In 1910 she was released on parole, promising not to take a position as cook again. She disappeared from view, but failed to keep her promise, and now has been again quarantined in North Brother Island.

Health of the Canal Zone.—The report of Dr. Charles F. Mason, chief health officer of the Canal Zone, for the month of January, gives the number of deaths from all causes among the employees as 17, of which 13 were from disease. This is equivalent to a death rate of 4.38 per thousand, as compared with 3.64 for the preceding month and 4.87 for the corresponding month of last year.

Death Rate in New York City.—During the week ending March 20 there were 1,743 deaths in this city, making a death rate of 15.66 per 1,000 of the population, which compares favorably with the figures for the corresponding week last year, during which 1,757 deaths were reported, making a rate of 16.42. The death rate for the first twelve weeks of 1915 was 14.09, as against a rate of 15.53 during the corresponding period of 1914.

Negro Death Rate too High.—Figures prepared by Dr. William H. Guilfoy, Registrar of Vital Statistics, show that the general death rate among the negroes here is almost double that of the city at large. In 1914, out of 74,803 deaths, 2,631 were those of negroes. As the total negro population of the city is about 100,000, this gives a negro death rate of 26.31 per 1,000, as compared to the general city death rate of 13.40 per 1,000 during the same year.

Sale of Christmas Red Cross Seals.—Reports to the National Association for the Study and Prevention of Tuberculosis up to March 1 indicate that the sale in the entire country will exceed 52,000,000 seals, an increase of 7,000,000, or 15 per cent., over the previous year. Winners of pennants for the best per capita sale of Red Cross seals in 1914 are announced to be: Garden City, N. Y., in Class A, population 500 to 2,000; Sewickley, Pa., in Class B, population 2,000 to 8,000; Charleston, W. Va., in Class C, population 8,000 to 25,000; New Rochelle, N. Y., in Class D, population 25,000 to 50,000; Troy, N. Y., in Class E, population 50,000 to 150,000; Rochester, N. Y., in Class F, population 150,000 to 500,000; and Pittsburgh in Class G, population over 500,000.

Proposed Consolidation of Tuberculosis Hospitals.—It is reported that Col. George Bushnell, Medical Corps, U. S. A., commanding the General Hospital, Fort Bayard, N. M., has been designated to inspect tuberculosis hospitals of the Navy and the Public Health Service, as a preliminary step in their proposed consolidation with the Army hospital.

The Health Department Aids in the Diagnosis and Treatment of Meningitis.—The attention of the physicians of New York City has been called to the fact that the Department of Health in its Division of Preventive Medicine and Specific Therapy (Bureau of Laboratories) maintains a staff of physicians and bacteriologists who have made a special study of meningitis. The services of this staff are at the disposal of the practising physicians of this city in the diagnosis and treatment of meningitis and meningeal conditions. The patients are seen only in consultation, for the department has no desire to supplant the private physician in charge of the case. Moreover, since in most instances the family cannot give adequate assistance in doing a lumbar puncture and administering serum, the presence of the family physician is most valuable. Any physician wishing the service of this staff in the diagnosis and treatment of meningitis or meningeal conditions should telephone Stuyvesant 1600.

Obituary Notes.—Dr. Edward Sprague Peck of New York, a graduate of the University of Vermont, College of Medicine, Burlington, in 1868, consulting surgeon to the City Hospital, ophthalmologist to St. Elizabeth's Hospital and the Montefiore Home, and a member of the New York State and County Medical Societies, the Northwestern Medical and Surgical Society, and the Physicians Mutual Aid Society, died at his home on March 25, aged 67 years.

Dr. Oliver Cotton Smith of Hartford, Conn., a graduate of the Long Island College Hospital, Brooklyn, in 1883, consulting surgeon to the Litchfield County Hospital, visiting surgeon to the Hartford Hospital, a member and president of the Connecticut State Medical Society, a member of the American Medical Association, the Hartford County Medical Society, the American Urological Association, and the New England Branch of the American Urological Society, and a fellow of the American College of Surgeons, died at his home, from cancer, after a long illness, on March 27, aged 55 years.

Dr. Joseph Francis Bloodgood of Flushing, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1884, attending surgeon to the Flushing Hospital, and a member of the New York State and Queens County Medical Societies, the New York Academy of Medicine, the Greater New York Medical Society, and the Associated Physicians of Long Island, died at his home from pneumonia, after a short illness, on March 12, aged 55 years.

Dr. Jones Cadwalader Abernathy of Birmingham, Ala., a graduate of the Tulane University of Louisiana, Medical School, New Orleans, in 1860, surgeon in the Thirty-second Alabama Regiment throughout the Civil War, and a member of the Medical Association of the State of Alabama and the Jefferson County Medical Society, died at his home suddenly, on February 27, aged 79 years.

Dr. Harry Garrison Plymire of South San Fran-

cisco, Cal., a graduate of the College of Physicians and Surgeons, San Francisco, in 1900, coroner and public administrator of San Mateo County for three terms, died at his home, after a short illness, from pneumonia, on February 27, aged 38 years.

Dr. THOMAS HENRY MAGUIRE of Boston, Mass., a graduate of the Harvard University Medical School in 1900, and formerly house physician at Carney Hospital, died at his home in Dorchester from pneumonia on March 5, aged 38 years.

Dr. RICHARD GORSHEL of Chelsea, Mass., a graduate of the College of Physicians and Surgeons, Boston, in 1894, died on February 20, from heart disease.

Dr. LUTHER GRAVES CHANDLER of Townsend, Mass., a graduate of the Harvard University Medical School in 1871, a veteran of the Civil War, formerly a member of the Board of Health of Townsend, and a member of the Massachusetts and Worcester North District Medical Societies, died suddenly at his home on March 1, aged 70 years.

Dr. ORRIS E. HERRICK of Grand Rapids, Mich., a graduate of the Albany, N. Y., Medical College in 1871, a member of the Michigan State and Kent County Medical Societies, and attending surgeon to the United Benevolent Association Hospital, died at DeVore Hospital, Grand Rapids, from paralysis, on March 5, aged 68 years.

Dr. WILLIAM GOLDSWORTHY of Duluth, Minn., a graduate of the University of Minnesota, Medical School, Minneapolis, in 1897, died at his home after a long illness, on March 4, aged 38 years.

Dr. WILLIAM W. MOSLEY of Richmond, Mo., a graduate of the University of Louisville, Medical Department, Louisville, Ky., in 1846, a veteran of the Civil War, and State Senator for two terms, died at his home on February 26, aged 90 years.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HUNTERIAN LECTURES, COMMEMORATION OF THE TWO BROTHERS AT ROYAL COLLEGE SURGEONS AND THE SOCIETY—HYDRONEPHROMA—ADDISON'S DISEASE—RODENT ULCER.

LONDON, March 12, 1915.

MR. Blakeway's Hunterian Lecture this year was on the "Treatment of Cleft Palate," which has of late years given rise to great differences of opinion, revealing dissatisfaction among practitioners, not to say inability to estimate the value of the several operations that have been advocated by different suregons. Le Monnier sutured successfully in 1764. Graefe cured a cleft of the soft palate in 1816. Ebel operated next year without success. Roux's first staphylorrhaphy dates 1819 and somewhat later Warren of Boston succeeded. Fergusson deliberately based his operation on anatomical grounds gaining by dissection of the muscles of a cleft palate in an adult, and divided certain of those muscles so as temporarily to relieve the halves of the palate from their traction. His method was at once generally adopted. By the middle of the last century median suture was performed much as it is to-day. It differs in two essentials from Langenbeck's—it is done much earlier and generally under anesthesia, both of which advances are owing to the late Sir Thomas Smith, who urged doing it before the patient could speak, and employed chloroform. The turn-over flap operation differs somewhat. One of the flaps from the oral surface of the palate is turned over like the leaf of a book, continuing attached along the edge of the cleft, so the raw surface looks downwards and the mucous membrane surface upwards. Operations of this kind have been done at various times since 1824. The claims were rviewed by Mr. Blakeway, who found but little evidence in support of them. The statement that they are life saving has not been proved. The suggestion that the worst cases can be closed only by early flap is not decided, it lacks proof, it is denied by Mr. Berry, who has had experience second to none. Moreover, the assertion that when done at the earliest age the speech is much better than when deferred, has yet to be proved.

You no doubt recollect that we have here a Hunterian Society founded to commemorate the work of two distinguished brothers—William and John Hunter. Both made great additions to our knowledge, many of the utmost importance, working much in the same manner, with the same energy, and in more or less the same direction. The society is not connected with the celebration of the younger brother, John, by the Royal College of Surgeons, the trustee of his wonderful museum, but employs similar methods in honor of him and his elder brother. Thus the society gives Hunterian orations in commemoration of William and John just as the Royal College of Surgeons adopts this method of keeping in the memory of successive generations the origin, progress, and needs of the great museum and the remarkable work of its founder.

To the notice of this year's oration at the college I will now add something about that at the society which was delivered by Dr. Russell Andrews, F.R.C.P., obstetric physician to the London Hospital. Like some of his predecessors, though treating of the brothers, he gave prominence to William, who was the elder by ten years and to some extent the teacher of his younger brother, at any rate in his earlier medical studies. It must seem natural to devote the chief attention to William, considering the ample exposition of John's work which is so often before us. In 1746 we find William Hunter lecturing on surgery and anatomy to a society of navy surgeons and practising midwifery, not exclusively, but with special interest in that branch. Two years later he made a continental tour. In 1748 he became physician-accoucheur to the Middlesex Hospital and the next year to the British Lying-in Hospital. Subsequently he took the M.D. and the Faculty Diploma at Glasgow and settled down to practise in London. In 1756 he took the license of the Royal College of Physicians and on this a very curious peep into past medical manners comes to light—the surgeons were offended at what they regarded as his desertion of them and they imposed upon him a pecuniary fine—actually £20. Does it not look incredible in this age of multi-qualification? In 1764 he was appointed Physician Extraordinary to the Queen—the first male to attend a queen in her confinement. In 1767 he was made a Fellow of the Royal Society and the next year began his buildings, which eventually included lecture and dissecting rooms as well as his museum and house.

His reputation in midwifery has rather overshadowed his other attainments, particularly, perhaps, anatomy, which he continued to study by dissecting for his lectures and for the preparations of his museum. He was also a diligent collector—manuscripts, coins, books, pictures, engravings,

curios, little came amiss. He is said to have spent £100,000 on his museum.

His brother John worked with him on this museum for about ten years and during that period we cannot doubt acquired the tastes, the methods, and the determination which enabled him to carry on the same researches which eventually brought about the still larger collection he gathered.

Hydronephroma has been before the Royal Society of Medicine in two papers. One brought forward by Dr. Frederick Taylor related a case in a man of 59, admitted to the Seamen's Hospital in November, 1907, with pulsating swellings of right elbow, right shoulder, and right gluteal region with hematuria. Systolic murmurs were audible over the tumors, which increased in size, the patient getting weaker. In the previous January he had passed clots with the urine with pain which ceased after their passage. The urine was then clear for two months, when another attack occurred and afterwards other clots and strangury appeared every five or six weeks with much suffering. Later another tumor appeared on the left side. This and the right both increased until they nearly met over the sacrum. The case continued to get worth until death in September, 1908. At the post mortem fractures of the bones at the sites of the swellings were found. These tumors on section were lobular, dark, and mottled from hemorrhage. There were nodules in the lungs. Cardiac valves sclerosed, inner coat of aorta atheromatous. In the upper third of the left kidney a spherical lobulated tumor, another separate one in the left suprarenal capsule.

In the other case, which was bilateral in a man of 49, there was secondary thrombosis of the inferior vena cava and terminal uremia. Both suprarenal glands and kidneys were infiltrated and there were secondary nodules in the liver and lungs. This case was related by Dr. Parkes Weber, who said the patient died from uremia and almost complete anuria and it was remarkable that he lived so long as he did; in spite of the condition of both kidneys his urine continued to be passed in fair quantities with very little albumin until a few days before death. The end seems to have been brought about by the complete venous thrombosis of the right kidney. As in other cases of thrombotic obstruction of the inferior vena cava, enlargement of the superficial veins on the front of the abdomen had been a striking symptom during life. The thrombosis may perhaps have begun in the veins of the greatly diseased and enormously enlarged left kidney, involved both renal veins and both hepatic veins and the whole length of the vena cava, the clot extending continuously from the iliac veins upwards to the heart for the upper end projected into the right auricle. Microscopic examination of the clot close to the heart showed it to be infiltrated from the malignant tumor.

Dr. Weber also read at the same meeting an account of a case which he called latent Addison's disease. The patient was a man of 35 who died with symptoms of pneumonia at the right base and some crepitation but no dulness at the left base. Much debility and later signs of empyema on the right side; at the post mortem the heart was found greatly enlarged and weighed 25 ounces. This was probably due to old chronic interstial nephritis. The suprarenals were both occupied by necrotic caseous material which involved the whole of the medullary substance and was covered by only thin layers of live cortex. This condition with the cardiac hypertrophy had apparently counteracted the tendency towards very low blood pressure, which equaled in this case 155—170 mm. Hg. But his debility was characteristic.

At the Harveian Society on the 25th ult. Dr. Graham Little read a paper on Rodent Ulcer, which had been described by Jacob in 1827. He complained that of late confusion had been caused by some who tried to turn a clinical group into a microscopical entity. It was better to return to Jacob's clear idea and regard as rodent ulcer all cases of ulceration of epitheliomatous tumors in which the cardinal symptoms were slowness of ulceration with absence of glandular invasion. He had had about 100 cases in hospital and private practice—most of them between 40 and 60 years of age. Mentioning several methods of treatment he gave the preference to that of freezing by carbon dioxide snow, considering it compared favorably with any other for safety, convenience, rapidity, and permanence. Quoting the truisms that some types of rodent ulcer advanced in spite of all treatment he admitted having failed in some with every recognized method in succession. Afterwards he exhibited three cases cured apparently by actual cautery, zinc ionization, and carbon dioxide snow respectively.

1. Progressive Neuromuscular Atrophy.—F. F. Hatch notes that the characteristics of this affection as originally described by Charcot and Marie are: (1) Progressive muscular atrophy beginning first in the feet and legs, not appearing in the hands and arms until several years later, the progression of the atrophy being slow. (2) Relative integrity of the muscles near the trunk, or at least much longer preservation of these than of the muscles of the distal ends of the limbs. (3) Integrity of the muscles of the trunk, shoulders and face. (4) Fibrillary contractions in the atrophying muscles. (5) Vasomotor disturbances in the portions of the limbs which have atrophied. (6) Absence of pronounced contractions of the tendons. (7) Sensations usually intact but sometimes affected. (8) Reaction of degeneration in atrophying muscles. (9) Hereditary and familial tendencies.

2. The Gold Sol Test of Lange in Cerebrospinal Fluid.—H. C. Solomon and E. S. Welles state that the test is performed by the addition of a preparation of colloidal gold to ten dilutions of spinal fluid, ranging from 1/10 to 1/5120, the results reading according to the change in color ensuing. Where no change occurs the reaction is called negative and recorded as 0. The color changes, depending on the amount of gold precipitated, are recorded as 1, 2, 3, 4, 5, the latter being clear, due to all the gold being flaked out. In the clinical application of the gold sol test it has been shown that different inflammatory processes of the central nervous system give reactions differing in the amount of color change and in the dilutions in which the color change occurs depending on type of condition existing. Thus

syphilitic disease of the central nervous system characteristically gives a reaction in the first five dilutions; tuberculous meningitis, as a rule, tends to react in the middle dilutions; while the meningitides of pyogenic origin often show the reactions in the high dilutions. Further, general paresis usually gives a characteristic reaction differing from that of cerebrospinal syphilis or tabes. Cases that are clinically fairly stationary give the same results ante and post mortem with the gold sol test. Post mortem spinal fluid from cases of general paresis will usually give the typical "paretic reaction," such as given by similar cases ante mortem. Post mortem spinal fluid from cases of a non-inflammatory nature may give the expected negative reaction; but "unexpected" positive reactions are obtained with certain post mortem spinal fluids, as are found with certain ante mortem fluids from similar types of cases. The results obtained with post mortem fluids tested by the gold sol test of Lange are comparable to those obtained with the ante mortem spinal fluid and when the body is well preserved, or the fluid obtained early, the results are the same as would have been obtained just prior to death. The gold sol test has the same value in the examination of cerebrospinal fluid obtained post mortem from the lumbar region as ante mortem, and the results may be similarly interpreted for diagnostic purposes.

1. **Intestinal Stasis, Bands, Kinks, and Membranes.**—R. A. Keilty and A. J. Smith note that these "bands" are of three types: congenital, developed hypertrophies, and inflammatory. Intestinal toxemia is common, the result of stasis, brought about primarily by the traction of these various bands, producing intestinal hypertrophy, with secondary fatigue or degeneration and dilatation. The condition occurs in the well nourished as well as in the neurasthenic. Intestinal ptosis occurring with general visceroptosis is merely an exaggerated type of the simpler forms. The various possibilities must be clearly understood and each individual case carefully studied before any treatment is inaugurated. When surgical means are applied, the mechanism must be clear, else the result will be worse than the original condition. Finally, at operation the entire abdomen must be carefully explored, because these conditions rarely affect one region without another.

2. **Hematogenous Infection of the Kidney.**—G. E. Brewer concludes first, that during the progress of any acute infectious disease a certain number of microorganisms find their way into the blood current, and that many of these organisms are excreted through the kidneys. If the number of these organisms is comparatively small, if their virulence is low, and if the kidneys are in a healthy condition, the transit of the organisms through the renal apparatus gives rise to no demonstrable lesion. If, on the other hand, the number of organisms is large, if their virulence is high, or if one or both kidneys are diseased, lesions are produced which may at the outset produce an overwhelming and fatal toxemia, or may proceed more slowly to the development of any of the classical types of renal infection or suppuration; second, that while the disease may be bilateral, in a large number of instances it is unilateral, and that its unilateral character is due to the fact that the affected kidney has lost to some extent its normal resistance to infection by trauma, abnormal mobility, previous disease, calculus irritation, anemia, passive hyperemia, complete, incomplete, or intermittent hydronephrosis; third, that the presence in the body of a kidney damaged by trauma or disease to such an extent as to lower its normal resistance to infection is a distinct menace to the individual, in that it possesses a potential susceptibility to even the mildest forms of blood infection; fourth, that while the author has been able to produce these lesions in animals by *Bacillus coli, Streptococcus pyogenes, Staphylococcus pyogenes aureus, Bacillus typhosus*, the pneumococcus, and the pyocyaneus, in clinical cases he has only been able to isolate the first four of these organisms. In the number of clinical cases the results of bacterial investigations have been negative, notably in one instance in which the disease was known to be a sequel of scarlet fever.

6. **Abdominal Symptoms in Pleurisy and Pneumonia.**—J. Dorning points out that the pain in pleurisy or pneumonia may be referred to almost any part of the abdominal cavity or it may be distributed over its whole area; most frequently it is limited to the right side or to the epigastric region, and when associated with considerable local tenderness and marked rigidity of the abdominal walls and an absence of noticeable respiratory symptoms, the attention may become so riveted on the painful region that only a superficial examination of the chest is made or the possibility of a pulmonary inflammation is entirely disregarded. It is believed that an explanation of these painful abdominal symptoms may be found in an irritation, or in an actual inflammation of one or more of the lower six intercostal nerves. The character of the pain is not always a reliable guide in the differential diagnosis, especially in children. The sharp, stabbing pain in the upper waist line, usually so expressive of a pleurisy, may sometimes be due to a peritoneal inflammation; and the colicky or dull aching pain typical of a peritoneal irritation may be caused by a diaphragmatic pleurisy.

7. **An Iodine Fumigator.**—W. L. Capell has devised an instrument of this kind consisting of a hollow cylinder, two and one-half inches in diameter, made of copper, with an opening in the top, closed with a cork. From opposite sides project hollow copper arms To one of these arms is attached a rubber bulb, and to the other arm a rubber hose. A glass nozzle and spirit lamp complete the instrument. The cylinder is for the purpose of vaporizing the iodine. The rubber bulb forces the air into the cylinder, which in turn forces the fumes through the opposite arm. The rubber hose is for the double purpose of giving flexibility to the arm and attachment to the nozzle.

9. **Venesection in the Treatment of Epilepsy.**—I. Bram believes that essential epilepsy is to be attributed to nervous instability which is accompanied by, and is probably the result of, an abnormally high intracranial pressure. An attack or fit is probably consequent upon a sudden increase of blood pressure (general) above the patient's usual pressure, associated with a tremendously high increase of intracranial tension. The treatment of epilepsy by drugs in the usual case is futile; the usual medicinal measures do more harm than good. The reduction of intracranial pressure by the removal through venesection of a quantity of blood sufficient to overcome the plethora and high blood pressure appears the most rational measure to employ. This treatment not only relieves the patient, but seems to favor a complete cure by overcoming the epilepsy habit. The frequency of venesection and the quantity

of blood to be removed at a sitting depend on individual circumstances. Dietetic and hygienic measures should supplement the treatment in every case. Occasionally the administration of thyroid extract or potassium iodide may also be deemed advisable as a supplementary measure.

1. Procedures Following Nephrectomy.—W. J. Mayo notes that injuries to the third portion of the duodenum may occur during right nephrectomy. Perforation of the duodenum may occur as the result of the attempt to secure the pedicle for the purpose of ligation. As soon as the diagnosis is established the abdominal cavity should be opened through the anterior abdominal wall, the peritoneum incised to the right of the curve in the duodenum, the duodenum itself elevated from its retroperitoneal bed at its outer side and the duodenal opening closed directly by suture. The author has devised a method of ligating a deeply placed pedicle of the kidney by means of the use of two clamps. In the management of the ureter after nephrectomy for tuberculosis the rule should be that when the kidney removed for tuberculosis is still secreting urine, if there is any evidence of mixed infection, the better practice is to attach the stump to the skin to prevent the possibility of wound infection with tuberculosis and sepsis. In just such cases the ureter will be found enlarged and softened, but not shortened or rigid. Subsequently, the ureter will often discharge more or less for some days or even weeks, but in practically all the cases it will heal spontaneously. Those which fail to do so can be removed at a secondary operation very conveniently from in front and the removal is greatly facilitated by its anterior attachment. In a considerable number of cases in which the author attached the ureter to the skin there has been no pain or inconvenience from it beyond the necessity of wearing a little pad of absorbent material over it, should it discharge for a short time.

5. Cancer in the Light of Recent Research.—H. R. Gaylord states that one of the most fruitful advances in cancer research must be a realization of the fact that cancer no doubt represents a great group of pathological changes having many points of similarity which have led to a classification under one head, cancer. Within this group there must be a great range of agents, probably a number of specific viruses which have yet to be discovered and studied. The cancer problem will never be taken by assault, as Ehrlich once stated, but it will be broken up into a great field which will require many years of patient and extensive work of many investigators.

6. Syphilis and Insanity.—E. B. Vedder and W. H. Hough have made a study of the prevalence of syphilis among the 1,283 inmates of the Government Hospital for the Insane, and reach the following conclusions: Syphilis among the white women in this institution is comparatively rare. Among white men the presence of syphilis has been demonstrated in 20 per cent. of the cases. At least 30 per cent. of white males in this institution are syphilitic. At least 10 per cent. of the insanity in this institution is directly attributable to syphilis.

8. Involvement of Nervous System During Primary Stage of Syphilis.—U. J. Wile and J. H. Stokes conclude that the nervous system may be and probably is frequently involved before there are other evidences of the hematogenous spread of the *Treponema pallidum* from the site of the initial sore. Such involvement may be slight as far as clinical symptoms go, and may not be accompanied by changes in the spinal fluid, as measured by our present methods. Serious involvement, however, may occur extremely early with very marked changes in the cerebrospinal fluid, and with definite impairment of nervous function. The clinical changes most commonly noted in this preroseolar period are: headache, involvement of the second and eighth nerves, and increased reflexes. Of these, the headache is most commonly associated with demonstrable changes in the spinal fluid. Absence of any of the three accepted criteria of nervous system involvement in the spinal fluid can be accepted as indicating the absence of syphilis of the brain, meninges, or cord only when a careful examination fails to reveal any symptoms pointing to involvement.

9. Treatment of Intestinal Amebiasis.—G. I. Jones is convinced that emetine hydrochloride, while a valuable amebicide, if used alone will not cure amebic dysentery and that relapses will soon occur. The same statement is equally true of ipecac used alone. After an experience with each of these drugs used alone the author has reached the conclusion that emetine given by hypodermic injection, accompanied or followed by the use of ipecacuanha by mouth, will cure most cases of intestinal amebiasis.

10. Unusual Case of Sinus Thrombosis.—H. Herman and M. J. Ballin report a case of this condition in a boy aged eight and one-half years. There was a history of a mild aural discharge from both ears of one week's duration, three weeks prior to admission into the hospital. There was a complete absence of all active otitic manifestations and clinical symptoms indicative of a sinus thrombosis. The finding of a positive blood culture containing hemolytic streptococci permitted the tentative diagnosis of a sinus thrombosis. Although the history and course of this case suggested an otological origin, a definite diagnosis of lateral sinus thrombosis, in the absence of a positive blood culture, was practically impossible. Acute pyelitis, malaria and typhoid fever were all excluded, and yet before the result of the blood culture it was not considered justifiable to attempt operation for only a suspected sinus disease. The blood culture taken one day before operation was positive; one taken a few hours before operation negative. The result of the latter culture is explained on the generally accepted theory that, in a case of bacteriemia of pyogenic origin in which there is a distinct focus of pus, bacteria may be disseminated into the blood stream from the original focus, only at certain intervals, these crises manifesting themselves clinically by chills, sweats and a very high temperature. In these cases bacteria may sometimes be demonstrated only at the height of the temperature. The authors allude to the importance, as demonstrated in this case, of the finding of bacteria in a blood smear according to the method devised by Sophian and Fried. The fourth unusual feature of this case was the continuance of the septic temperature for weeks after the removal of the thrombus.

2. A Case of Multiple Pulsating Tumors Secondary to Hypernephroma. F. Taylor.
3. A Consideration of Some Elementary Principles Involved in the Treatment of Soil-Contaminated Wounds. A. G. R. Foulerton.
4. A Case of Phenacetin Poisoning; Recovery. P. Hamill and T. G. M. Hine.
5. Two Cases of Traumatic Hemoperitoneum. C. Hamilton Whiteford.

1. The Operative Treatment of Cleft Palate.—H. Blakeway discusses the relative merits of the operation of "median suture" and the "turn-over flap" operation. The former as now performed differs in only two essentials from Langenbeck's practice—it is performed at a much earlier age and almost always with the aid of a general anesthetic. The author reviews the evidence concerning the claims put forward on behalf of the flap operation. The evidence is remarkably little. The statement that the operation is life-saving has not been proved. That because of the overlapping of flaps and the absence of tension union is more easily secured than by the operation of median suture is suggested by Goyder's series of cases, but the series is a small one, and the details given are in several respects meager. The suggestion that the worst cases of cleft palate can only be closed by a flap operation in early infancy is difficult of decision. Finally, the expectation that on account of the early age at which the operation can be done the speech will be much better than in cases where operation has been deferred to a later date has not yet been realized.

2. Pulsating Tumors Secondary to Hypernephroma.—F. Taylor reports the case of a sailor aged 59 years who had pulsating swelling of the left elbow, the right shoulder, and the right gluteal region, together with hematuria. The course of the illness was uniformly downwards. The tumors gradually increased in size and the patient became paler and weaker. The hematuria was intermittent and even for long periods absent. At autopsy there was found occupying the upper third of the left kidney a spherical tumor two and a half inches in diameter, which on histological examination proved to be a so-called hypernephroma. The other tumors all had the same structure. The pulsation is presumed to be dependent upon the high degree of vascularity.

3. Treatment of Soil-Contaminated Wounds.—A. G. R. Foulerton has performed a series of experiments to test the practicability of inhibiting the activity of anaerobic organisms by means of nascent oxygen evolved from sodium perboñate; the object being to combat the development of tetanus and emphysematous gangrene which are so prevalent among the wounded in Flanders and France. As the result of these experiments it appears that when there is opportunity for the early treatment of a recently soil-contaminated wound, and before the probability of any active vegetation of spores has to be considered, a thorough insufflation with sodium perborate, after any necessary preliminary cleansing, will effect all that is required in the way of inhibiting the activity of anaerobic bacteria; also the growth of other species which may be present will be checked by the action of nascent oxygen. In hospital practice, the insufflation could be repeated at intervals of less than 24 hours; but consideration of the experimental results suggests that if the perborate is applied freely there will be a continuous evolution of oxygen for the full period of 24 hours. Meanwhile, the dressing should be of the highest possible description, and not more than is necessary to absorb discharges. If, on the other hand, the wound does not come under treatment until it may be reasonably supposed that there has been opportunity for the vegetation of anaerobic bacteria, and for establishment of infection of the wall of the wound, insufflation with the perborate should be preceded by thorough cleansing of the wound and swabbing out of the cavity with pure phenol, in the hope of destroying any anaerobic bacteria which already may have established themselves in the tissues.

6. Removal of Eyes in the Presence of Orbital Cellulitis. W. T. Lister.

1. Application of Strong Antiseptics to Wounds.—C. J. Bond has tested the effect upon incisions made for the removal of varicose veins, of the application of strong antiseptics such as carbolic acid and tincture of iodine. There was no difference between the wounds so treated and wounds not treated in this manner as regards painful sensations and as regards the process of healing. The question now arises, whether the application of a strong antiseptic to an infected wound materially adds to the difficulties of the defensive cells in their struggle with the disease organisms on the one hand, and in their effort to remove cell debris and regenerate new cells on the other. The problem is one of balance of advantage. If the antiseptic destroys or inhibits the growth of the invading organisms, it promotes healing, even if it kills a few more tissue cells. If, however, it damages a considerable number of defensive cells and fails to destroy or inhibit the growth of the disease organisms, it will do more harm than good. The result in any given case depends to a considerable extent on the variety and numbers of the invading organisms, also to some extent on the amount of injury to the tissues, but it depends less on the kind of antiseptic employed than on the time which has elapsed between the infection of the wound and the application of the antiseptic, or, in other words, the extent to which the disease organisms have established themselves in the wound and invaded the tissues.

2. Treatment of Pernicious Anemia by Salvarsan.—Byrom Bramwell adds to the twelve cases already reported by him in which this method of treatment was employed in nine other cases. For comparing the results obtained with these following the treatment by means of arsenic administered by the mouth, the impression gained was that the former method is decidedly superior. Salvarsan or neosalvarsan were given intramuscularly. Salvarsan was apparently the more effective of the two drugs. One advantage which both have over the long-continued use of arsenic by the mouth is that salvarsan or neosalvarsan do not produce peripheral neuritis or the other toxic symptoms resulting from the long-continued administration of arsenic.

3. Benzol Therapy in Leucemia and Lymphosarcoma.—T. G. Moorhead reviews the history of this method of treatment and reports four cases of his own in which it was employed. Von Koranyi was the first to use benzol in leucemia basing this therapy upon the observation made by Selling that among the manifestations of benzol poisoning there are a striking diminution in the number of white cells, the polymorphonuclear cells being diminished out of all proportion to

the lymphocytes, and a moderate anemia. The conclusions derivable from von Koranyi's cases and those of others are summarized as follows: Benzol first tends to increase the number of white blood cells, but shortly leads to an improvement of the leucemic condition. The decrease in white cells is at first slow and later more rapid, and may proceed in an irregular manner. Once the decline in number of white cells has started, it tends to continue for some time, even if the benzol is stopped. As the white cells diminish in number, the differential count both in splenomedullary and in lymphatic leucemia approaches more nearly to the normal, but as a rule some myelocytes persist in the splenomedullary disease, and in the lymphatic form the lymphocytes continue to be excessive in proportion to the other white cells. In short, even when the total number of white cells is reduced to normal, the differential count shows the presence of some leucemic characteristics. The average dose of benzol that may be administered with safety is from 3 to 5 grams daily. It is best given in gelatine capsules, combined with an equal quantity of olive oil, which seems to lessen the tendency of the benzol to produce heartburn and gastric irritation. The effect of benzol on the spleen in splenomedullary leucemia is variable. In some cases the spleen diminished almost to normal; in others, even when the blood picture is reduced almost to normal, the spleen remains large. The ultimate result in apparently cured cases of leucemia is still to be waited for. There is as yet no proof that the cure produced is of a permanent nature. One case of von Koranyi's was reported as quite well ten months after the cessation of the treatment.

Practical Viewpoints in the Treatment of Tetanus.—Heile has thus far seen 12 cases of tetanus with a mortality of 5. The others all recovered completely. The treatment consisted of antitoxin and magnesium sulphate. The supply of the former was too small to permit the use of large doses. In some cases even less than 100 units were available for a case. The shortage was evidently due largely to the universal prophylactic use of the serum. Not a single case of tetanus developed after this prophylactic wound treatment. In one series of severe wounds all received prophylactic injection but one, who alone developed the disease, the latter proving absolutely intolerant to treatment. This case although proving nothing is highly significant. In treating tetanus we should never await the development of the complete picture of the disease. A probability diagnosis should be sufficient. There is a possibility of acting upon the cause of the disease before it has become anchored in the central nervous system. The earliest symptoms are twitching or perhaps actual contractions in the affected limb; discomfort in the wound; excessive perspiration—which may be universal; slight dysphagia; rigid carriage of the head; slight slowness in sitting up from the recumbent position, and increased excitability of the tendon reflexes—especially of the wounded limbs. In this early period it is useful to make an endoneural injection. It is hardly necessary to isolate the nerve completely, and this is not always possible. The region of the nerve can be reached by infiltrating the locality between the ischial spine and ischial tuberosity. The brachial plexus can be infiltrated by Kuhlenkampf's method. But after the disease picture is fully developed only an intradural injection can be of any value. When the disease picture is not very pronounced simple measures suffice to control the disease (serum, magnesium sulphate), and patients recover. Either plan of management may be pursued alone as long as the patient does well. The magnesium is given intramuscularly, 3 to 6 gms. To state that mild cases can recover without any treatment is offset by the counterclaim that the mildest cases may suddenly pass into the gravest types. In passing it may be stated that the inverse order is seen, to wit: cases beginning with violence become milder. When the paroxysms become violent at any time this indication must be promptly met, lest the patient die of suffocation. The intraspinal use of magnesium sulphate is here indicated, but we have no idea of individual tolerance to this substance. Increase in the severity of convulsions is assumed as evidence of cumulative poisoning but have we any other criteria? The author believes such a one to be increase of reflex activity. This gives us a rational indication for the use of magnesium sulphate, and by the cord. The initial doses should be small, until some idea of tolerance is obtained. The technique given by the author is too long to be reproduced here (or better the reasons upon which his technique is founded). In autopsies of cases in which lumbal injections had been repeatedly practised, certain changes have been found in the cord. In other words, magnesium has two actions—physical and narcotic. The former has not been fully studied. The author's rule has been to use an increase of reflex irritability as a guide to renewing the injections. In but two cases could tetanus bacilli be found in the wound secretions even in the most malignant cases (incubation 3 to 8 days). One case of 21 days' incubation, contrary to the rule, also ran a malignant course, but it is possible that something occurs in these cases to rouse up latent bacilli in the wound. If this is true the term incubation has no radical significance.

New Method of Treatment of Tuberculous Meningitis.—Bacigalupo of Buenos Aires states that he can find in the literature but 22 cases of recovery following tuberculous meningitis. Concerning the general use of tuberculin he states that it is used almost universally by hypodermic injection. He quotes one case in which the drug was thrown into the trachea at the bifurcation for pulmonary tuberculosis in the stage of hepatization, and others in which the remedy was injected directly into surgical tuberculous lesions. The thought was close at hand to inject the drug into the serous sacs and especially in the case of tuberculosis of the meninges, into the dural sac. Various preliminary experiments were made from this viewpoint. An intradural injection was made upon a child dying of miliary tuberculosis with meningeal complications. The child showed some improvement in its cerebral symptoms but died on the third day. Soon afterwards two pure cases were seen—tuberculosis limited to the meninges, and tubercle bacilli in the cerebrospinal fluid. Tuberculin was injected intradurally, one child receiving two and the other three injections. In the course of 20 days both children were cured. In all three cases the temperature fell after the injection about 1° C. and did not rise again. Hence of the now 24 recoveries 2 have been brought about by the same man and same method —about 8 per cent. The author in his very brief communication omits the dose and technique.

Feeding the Civil Population in War Times.—Hanauer, like all writers on this subject, introduces novel statements and arguments. Experience has shown that in famine times deaths from all causes increase, thus showing that resistance to all noxious agents is diminished. It is probable that even very slight reductions in ali-

mentation may weaken this resistance in certain individuals. Over and above this component an imperfect dietetic requirement greatly disturbs the psyche. The people are dissatisfied; they are filled with hate and rancor, and are ripe for revolt. There was so much beef on hand when the war began that the menace of slaughter for the sake of sparing fodder was impending. The price of beef eventually went up, and the authorities enforced the law against killing animals below a certain age. Appropriations were made for sufficient fodder. Whenever slaughtering was done beyond demand the beef was to be converted into permanent food products. A fixed maximum price for fodder and beef has been demanded. The shortage of fodder will have to be made up from potatoes, beets, turnips, etc., and kitchen swill. The best way to insure a meat supply, however, is personal self-denial. Some animal waste can be utilized for food, and horses and rabbits can supply much protein. Naturally the middlemen must be eliminated in threatened famine, as they contribute greatly to the cost of food to the consumer. The author says the German will be better off in more ways than one if he can learn the art of proper mastication of his food.

Rare Forms and Complications of Plaut-Vincent Angina.—Reiche of the Hamburg-Eppendorf Hospital saw in twelve years 4,052 cases of acute anginæ, in 139 of which was found the Plaut-Vincent disease in pure condition, *i.e.* with absence of the diphtheria and other pathogenic microorganisms. In all these cases mouth and pharynx were alike involved. In two previous papers the part of this clinical material then on record gave quite constant finds, and only recently, with increased observation, have certain peculiar finds been noted. These include severe prostration, headache refractory to analgesics, a picture suggesting typhoid fever (fever, enlarged spleen), peculiar blood-pictures, disturbances of accommodation and other anomalies of the nervous system. Locally he noted destructive ulceration of the fauces. In a word, there are cases of this affection which in an epidemic of diphtheria might readily pass for the latter. In one case the blood picture suggested pernicious anemia, and the patient died apparently of this affection. This association has been remarked by several clinicians. These points of contact between the Plaut-Vincent stomato-pharyngitis and the three diseases, diphtheria, typhoid, and pernicious anemia, require further study.

Grazing Wounds of the Skull.—Noehte states that tangential wounds made by shrapnel bullets or shell fragments may be very superficial, but as a rule the missiles damage the portion of cortex beneath the wound. When the motor region is affected, or any other locality which has a peripheral expression (nystagmus, speech disturbance), we can comprehend objectively the nature of the brain lesion. These wounds, besides the local phenomena, may manifest themselves by general disturbances—anomalies of pulse and temperature apathy. Recognition of all these conditions is important for the treatment and for the just estimation of subsequent nervous difficulties which might affect claims for maintenance. Those wounded in this manner should not be classed with the slightly wounded, but as requiring bed rest and observation. The question of the integrity of these subjects cannot be answered in general. When all the subjective and objective phenomena of a cerebral injury have disappeared, it is safe to let the soldier return to his command.

Cardiopathic Hepatitis.—Heinrichsdorff sums up this condition as follows: in heart disease the liver is not only drawn secondarily into sympathy, since the blood stasis causes compression of the framework of the liver, but is also primarily influenced because the cardiac toxin is also an hepatic toxin which leads to acinous degeneration and perihepatitis. Hence the author substitutes the term cardiopathic hepatitis for stasis of the liver. There are acute and chronic forms. Acute cell degeneration appears in various forms—central fatty degeneration, with or without hemorrhagic changes; central necrosis with hemorrhage, coagulation necroses from vascular obstruction, etc., etc. From these acute forms chronic forms develop, characterized by more or less increase of connective tissue—fibrosis of the liver. The latter process tends to begin about the central veins, and, as a rule, on anatomical grounds there is an overgrowth of periportal connective tissue. The latter may be of a slight degree, but is often as marked as the central fibrosis. In a lobule the central and peripheral lesions tend to approach each other, so that an entire lobule may be uniformly involved. As a rule the parenchyma of the liver is not disturbed, but in certain cases changes occur like those in alcoholic cirrhosis of the liver. We see this if a stretch of hepatic tissue has been irregularly involved in the fibrosis. The changes are far less marked here than in alcoholic cirrhosis, but in both cases seem to be due to a breakdown of the parenchyma. The two components of cardiopathic hepatitis—stasis and toxemia—are not alone active in this condition, but also in tuberculosis and nephritis where there is cardiac stasis. Hence in addition to simple cardiopathic hepatitis, we see cardiac stasis with tuberculous cirrhosis of the liver, and complications of cardiopathic hepatitis with renal or vascular disease.

The Calvé-Perthes Disease.— Michelsen states that this affection was described independently in 1913 by the two authors concerned. He adds to the recorded material five personal cases. The affection is very rare, and nearly all patients are boys about the age of 5 to 10. Either after a trauma or without apparent cause the children begin to limp and, in fact, behave just like those with incipient tuberculous coxitis. However the complete absence of positive biological finds has led to the separation of this condition as being one *sui generis*, and this view has been corroborated by *x*-ray finds. Of its causation we know nothing. Rickets can be excluded, while the evidence concerning traumatism is conflicting. There seems to be some similarity to Kohler's disease, save for the localization. In general the changes in the bones in the new affection seem identical with those in the scaphoid of the foot and patella as seen in Kohler's disease. If the three locations should be attained in the same subject we could simply enlarge the picture of Kohler's disease to include the hip joint lesion (and vice versa). No descriptive designation has yet met with general approval, so that the disease is named for its two discoverers. There has been one attempt to christen it according to scientific nomenclature—osteochondritis deformans juvenilis coxæ—but the author repudiates this.

Non-Ligation of the Umbilical Cord.—A. N. Rachmanow concludes on the basis of a five-years' experience comprising 16,000 deliveries that non-ligation of the umbilical cord in the method to be elected in normal labor and in the case of full term infants. It is safe and favorable, leading to a good cicatrization of the navel. Ligation of the umbilical cord is a therapeutic measure, Rachmanow says, to be reserved for pathological cases, such as prematurity and asphyxia in the infant and hemorrhages in the mother.—*Zentralblatt für Gynäkologie.*

Insurance Medicine.

THE GENERAL FACTORS DETERMINING MEDICAL SELECTION.

FROM "ALLGEMEINE LEBENSVERSICHERUNGSMEDIZIN"

BY PROF. DR. GEORG FLORSCHÜTZ OF GOTHA.

THE essential distinction between insurance medicine and medical practice is that the insurance physician is concerned as a rule with the recognition of the substratum of diseased conditions before the latter develop, while the general practitioner endeavors to interpret symptoms actually present. The medical examiner in the absence of symptoms on the part of the applicant, must make a further search for predisposing causes in order properly to estimate his chances of survival. No matter how many factors are present which influence the latter, the individual himself is always the first factor to be considered among those which influence the hazard. In his prognostic computations the examiner begins with him and brings him into reciprocal action with all other determining factors.

Heredity and Constitution.—The most important rôle in the prognostic judgment of an individual has always been the latter's constitution as far as it predisposes him to disease; this should be brought into relationship with heredity. Selection according to this principle was one of the earliest fundamentals applied in life insurance. It is not without interest to examine not only the old Insurance Acts, but also the literature used in former days, and now preserved in libraries. These were the authoritative medical fundamental views of that period which determined the medical selection which we study in its operation to-day and apply as a principle of selection at present. We find the following passage in Piorry's work (translated in 1841) "On Inheritance in Disease": "Latent morbidity is the quality of the human organism in virtue of which the same is inclined, through adventitious influences in certain maladies, to perish." Insurance medicine to-day could hardly add anything to this definition, even if latent morbidity, or the substratum of disease, is defined further as the peculiar quality of the body, in virtue of which certain physiological or pathological conditions have been handed down from parents to children and because of which the children possess a quite special tendency to perish from the diseases from which their parents or ancestors have suffered. One distinguished also between generic, individual, and special disease substrata; knew that these were responsible for the fact that the action of the same occasional cause was quite different in different individuals; knew finally that there are certain periods of life in which the disposition to disease appears in the foreground or again vanishes. However, one concerned himself very little with the anatomical substratum; it was the dyscrasia which stood in the foreground of the humoral pathological conception and which determined almost solely the thought of that period.

If we then note further that upon these basic views in medical insurance selection Virchow's cellular pathology could exert only a very superficial influence and bacteriology no influence at all, this no longer seems strange to us; especially if we can place ourselves in thought back in the last decade of the last century, and again represent to ourselves the attacks to which life insurance was exposed, because it held so firmly to the old traditions and would not allow itself to be converted to the view that merely by the study of the exciting causes of disease everything could be etiologically explained.

Indeed, nothing could be more destructive to their edifice than the denial of the foundation upon which they had learned essentially to estimate their risks; nor could there be anything more disheartening than in place of this objectively conceivable comprehension, to be compelled according to the new learning to set up only the contingency of bacterial invasion. Their own empirical investigations and the results laboriously acquired therefrom for selection would, according to this view, have been a great error, and the teachings drawn chiefly from animal experiment would then alone have been of significance. Were the estimation of the duration of life in mankind a play of chance, and had life insurance medicine not become rooted fast on its own investigations, the powerful onrush of bacteriology would have been a source of danger to it. But it had long recognized morbid tendency and heredity as the first and principal causes which determine longevity. It had also recognized further that where it encountered one of these causes its influence on life expectancy seldom appeared alone, but was accompanied by a series of conditions which might alter the cause and also its operation. These conditions were age, mode of life, financial status, sex, residence, and occupation; and it had become its constant scientific task to follow them up exhaustively in their reciprocal relations with the strength of constitution of the individual for the determination of the life expectancy in the individual risk.

To-day, however, there has again come a change in general medicine, nor is this change only of yesterday. We no longer study exclusively the exciters of disease; we once more study the peculiarities of the infected organism, and we now know that infection alone is not able to call forth disease; for it is before all pertinent that the infected individual be susceptible to disease, *i. e.* have a morbid tendency or substratum. To uncover this in its final causes is the task which biological and clinical investigators have set for themselves. Life insurance medicine cannot participate in these labors because it is not able to push causal research; and thus far it has indeed only a very conditional interest in them, for it is, in the last analysis, quite indifferent as to whether falling ill with tuberculosis is ascribable to a new exogenous infection or to an infection acquired in childhood which manifests itself as a metastatic autoinfection.

The only question which it sets itself to answer is: Are there ways by which we can recognize latent disease or the morbid substratum in the applicant for insurance?

In the first place it is the constitution to which the study of life insurance medicine is directed. It understands, under constitution, the quality of body which is outwardly expressed by body measurements—in other words, the *external configuration* of the body as conditioned by the nutritive processes; or, briefly, according to the old medical nomenclature, the *habitus*. The conception of the constitution by insurance medicine is therewith purely a quantitative one; and becomes qualitative only when the constitution in relation to the external influences brought to act upon the individual, shows qualities which indicate a tendency to disease or health.

(*To be continued.*)

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 23, 1915.

THE PRESIDENT, DR. HOWARD LILIENTHAL, IN THE CHAIR.

The Relation of Hernia to the Workmen's Compensation Law.—Dr. ALEXIS V. MOSCHCOWITZ read this paper. (See page 547.)

Dr. WILLIAM B. COLEY said that while he differed strongly with Dr. Moschcowitz in his theory as to the cause of hernia, particularly as regarded the relative frequency of a preformed or congenital pouch of peritoneum, they finally arrived at practically the same conclusions. The old word "rupture" was responsible for most of the current ideas of hernia held by the laity, and for not a little of the loose thinking on the part of the medical profession itself. When once an idea was firmly fixed in the minds of the laity, and if it remained unchallenged for several centuries, it was extremely difficult to eradicate it even when it was clearly proven to be false. Phioraunti in 1585, spoke of a great secret to help those who were bursting or had rupture. Vigo in 1543, in his chapter on "Rupture and Burstynge," described three groups of hernia: (1) Certain relaxation, which he called "lyttle rupture"; (2) relaxation which had become so "grosse as to cause payne and swellynge of the flanx to the size of an egg," this was called "rupture incomplete"; (3) in which the hernia had entered into the scrotum. As regarded the etiology, the causes were given as primitive and antecedent. Among the primitive causes were mentioned, a fall from a high place, a "stryke with a fist, staff, dagger, or foote." Among the antecedent causes were mentioned, "humoris phlegmon," meats that caused "gasses," cold in the feet, etc. All of these things caused "rupture" or "burstyng." Dr. Coley said that Dr. Moschcowitz, contrary to Hamilton Russell and others, placed less importance upon the presence of a funicular process of peritoneum or preformed sac, as an etiological factor in hernia. Personally, he strongly agreed with Russell, and his own operative experience at the Hospital for Ruptured and Crippled (nearly 5,000 operations, the great majority of which were children), strongly confirmed this view. He did not agree with Dr. Moschcowitz that it was possible to distinguish between the so-called acquired sac and the congenital or preformed sac by the character of its attachment to the cord structures. In inguinal hernia in children and in most adults, except in a case of long standing hernia, the cord was spread out in a fan-like manner, often covering the whole posterior wall of the sac, and while it might be said to be intimately connected with the sac, the sac could always be pulled off quite readily. There was no way of differentiating an acquired from a congenital sac. He believed that practically all cases of oblique inguinal hernia were primarily due to the presence of a funicular pouch or a preformed sac, extending in varying lengths into the canal, and in a considerable number of cases, communicating with the tunica vaginalis. This constituted not a real or actual hernia, but a potential hernia, and in some cases the external ring was so tight that the patient might live a long life and never have an actual hernia. On the other hand, with a large ring, or even one of moderate size, a small piece of omentum was forced wedge-like into the funicular process or pouch, and any increased abdominal pressure tended to force this wedge further into the pouch until gradually the external fascial ring became dilated, and for a number of months, and in some cases years, an actual hernia was forming—that was, a sac with contents, omentum or intestine. This was a slow and not a sudden process. The main point at issue in determining whether a hernia was the result of an accident, thereby probably coming under the Workmen's Compensation Act, was whether a hernia could be produced by a single application of force applied externally, or by a single increase in intraabdominal pressure. Nearly all authorities on hernia held that actual true traumatic hernia produced by external violence were of extremely rare occurrence, as Dr. Moschcowitz had already pointed out. Excluding the very small number of cases in which the patient was struck by a sharp instrument penetrating the abdominal wall, or fell upon some sharp object, which tore apart the fibers of the natural hernial opening, both of which would be associated with evidence of severe pain, local edema, and hemorrhage, traumatic violence could not be said to be the cause of hernia. Now came the second question, one that was far more important and had given rise to more dispute in a medicolegal way than any other, whether a hernia might be caused by a single increase in intra-abdominal pressure. MacReady, the greatest English authority on hernia, stated that an acquired hernia was never due to this cause. Graser, one of the highest German authorities, stated that a hernia complete in all its parts could never arise at the moment of accident, or by a single increase in the intra-abdominal tension, be it ever so great. Dr. Coley's own personal opinion based upon an experience of twenty-five years at the Hospital for Ruptured and Crippled, at which institution from 4000 to 5000 cases were observed annually, practically coincided with the opinions held by MacReady and Graser. He knew, however, of two exceptions to this general rule; one was a case presented by Dr. F. Tilden Brown before the New York Surgical Society, November 11, 1903. The question of hernia accidents had been carefully studied from a medicolegal standpoint by William Sheen (Practitioner, London, 1909, vol. lxxxiii, p. 334), who stated as follows:

"Excessive strain must be regarded as an injury," epitomized a judgment of the House of Lords, the highest tribunal in England, and it was to "excessive strain," generally from lifting, that a workman commonly attributed his hernia, or "rupture," as it was, as a rule, wrongly and most unwisely termed. Sheen analyzed the subject in a very lucid and practical way, and cited an ordinary case of supposed traumatic hernia in which claim for damages was brought against an employer or corporation. The claimant would say: "On such and such a date, at such and such a time, he lifted an unusually heavy weight, and felt a sensation of something giving way in his right groin. His fellow-workman was with him at the time, and he mentioned the matter to him. He finished his day's work. The same evening when washing, he found a lump in his right groin. The next morning he went to a doctor." Of course, variations in the history would occur. Nothing might be felt locally at the time of the supposed strain. It might be days or weeks after the strain that the workman discovered the hernia. The hernia, when found, might be large or small. The hernia might be attributed not to a strain, but to a blow in the groin, abdomen, or elsewhere, or to some other cause. The presence of a double hernia was sometimes attributed to a single strain. Sheen stated: "I consider that its sudden complete development, in a pathological sense, is impossible, because the peritoneum cannot stretch suddenly to form the sac. The sudden projection of hernial contents into the preformed sac is accompanied by definite immediate symptoms. The affected individual suffers acute pain at the site of the hernia, at once undoes his clothes, finds a small lump there, is faint, helped or carried home. The hernia is reducible with difficulty only, if at all, and is often strangulated. A doctor is at once sent for." Sheen concluded with the statement: "A hernia may be felt for the first time during a straining effort, and this is very likely to occur in the working classes who are constantly straining. This, however, is the occasion leading to the discovery of the hernia; it is not the cause." In his paper on "Industrial Accidents in Relation to the Development of Hernia," Dr. Coley made an analysis of 4,797 cases of hernia in adult males that were over fifteen years of age. The causes of hernia as given by the patients at the time of examination were as follows: 3,102 male adults stated that the rupture had appeared without any known cause. Of these 2,022 had inguinal hernia, single; 976 inguinal hernia, double; 55 femoral hernia; 18 ventral hernia; 31 umbilical hernia. One thousand and fifteen attributed the hernia to lifting or carrying some heavy weight. Of these, 692 were inguinal hernia, single; 291 inguinal hernia, double; 17 femoral hernia; 7 ventral hernia; 8 umbilical hernia. One hundred and fifty stated that the rupture was caused by coughing or sneezing. Of these, 106 were single inguinal hernia; 33 double inguinal hernia; 4 femoral hernia; 2 ventral hernia; 3 umbilical hernia. In 123 cases the cause was attributed to a push, fall, or twist; in 27 to straining at stool, constipation; in 89 to a fall from a height, horse bicycle, wagon; in 34 to slipping; in 40 to a blow in the groin or abdomen; in 8 to a kick; in 20 to running or jumping. Of 502 cases of umbilical hernia in adult women, in 2 ascites was supposed to be the causative

factor; in 3 obesity; in 6 a fall; in 8 coughing; in 195 pregnancy; in 188 the cause was unknown, and in one case the hernia had existed since birth. This analysis showed very much the same facts that Berger had recorded on a basis of his study of a similar group of cases observed of the Société des Bandages in Paris. They showed that nearly 70 per cent. of hernia in adult males appeared gradually without any known exciting cause. In these cases there probably existed a preformed sac of congenital origin, which gradually became dilated by the normal increase in intra-abdominal pressure consequent upon the daily routine of life.

The Theory of the Workmen's Compensation.—Dr. FREDERICK W. LOUGHRAN presented this paper. He stated that workmen's compensation legislation was based on the principle that the cost of industrial accidents, however caused, whether due to the negligence of the employer, of the employee, or of no one, was a necessary part of the expenses of industrial production which should be made a charge upon the industry, not upon the individual, and as such should be assessed in the first instance upon the employer in the form of a premium for insurance and by him passed on to the consumer in the form of an advance in price. This principle had long been embodied in the legislation of European states, but it was only within the last four years that it had been enacted into law in this country. The soundness of the principle was generally conceded by the economists, and once accepted and formulated into law it would never be abandoned. These laws provided a method of indemnifying workers injured in the course of their employment, which was more certain, speedy, economical, and equitable than the old liability system. The speaker showed that in the last analysis the latter system meant that an injured employee was obliged to fight a powerful organization thoroughly equipped with all the financial and legal resources to conduct a long contest in court. The odds in the game were heavily against the injured employee. Only one employee out of eight on an average ever recovered anything in an action for damages brought against the employer. Under the new system it was not necessary for the injured workman to go to court in order to secure compensation. He was not required to prove fault on the part of the employer or his superintendent. The doctrine of fault had been swept away. The burden of proof had been shifted from the employee to the employer. The 42 groups of hazardous employments included practically all occupations except domestic service, farm labor, and mercantile employments. The act provided compensation according to a fixed scale for all injuries received in the course of employment which entailed a disability of more than two weeks, except those occasioned by the wilful intention or by the intoxication of the injured employee. This waiting for two weeks was to prevent a workman from claiming a minor injury in order to obtain a vacation with pay. After two weeks compensation began and was two-thirds the average weekly earnings. In case of permanent total disability, the compensation was payable throughout the entire period of its continuance. In the event of death resulting from injuries received in the course of employment, the compensation was payable to surviving heirs under the age of eighteen years and to dependent parents or grandparents, under conditions as to amount and duration as specified in the act, the total amount in any case being limited to two-thirds the average weekly earnings of the deceased. Employers were not permitted to pay this compensation directly to their employees, but were required to insure this liability, and for this purpose three options were offered, namely, insurance in the State Fund, insurance in any stock or mutual company authorized to write workmen's compensation in this State, and self insurance under conditions provided by the Workmen's Compensation Commission. All claims must be presented to the Commission and all payments to employees were made by the same body. The speaker, after describing in detail the method by which the compensation was payable, considered the medical aspect of this law. He quoted Section 13 of the law which was as follows: "Treatment and Care of Injured Employees. The employer shall promptly provide for an injured employee such medical and surgical or other attendance or treatment, nurse, and hospital service, medicines, crutches, and apparatus, as may be required or be requested by the employee, during sixty days after the injury. If the employer fails to provide the same, the injured employee may do so at the expense of the employer. The employee shall not be entitled to recover any amount expended by him for such treatment or services unless he shall have requested the employer to furnish the same and the employer shall have refused or neglected to do so. All fees and other charges for such treatment and services shall be subject to regulation by the commission as provided in section twenty-four of this chapter, and shall be limited to such charges as prevail in the same community for similar treatment of injured persons of a like standard of living." It was pointed out that this immediate medical attention was a great advantage to both employer and employee as it lessened time of disability and emphasized the advantage of having healthy workmen and keeping them so. The community would be benefited as the workman and his family would not become public charges. On the other hand, it was claimed that in European states where such a law had been in operation for twenty years that new forms of nervous disease had arisen and that workmen had been accused of exploiting their injuries. European doctors had also been accused of using the Workmen's Compensation Law irregularly as a source of revenue. Of course this problem could only be solved by the co-operation of intelligent physicians. The object of the act was to return people to industry and one of the effects of the act was that people might refuse to go to work while in pain. The longer some of these injured employees, as for instance, a broken leg followed by contracture of the muscles, stayed away from work the harder it was for them ever to go to work, and it was not long until the atrophy became permanent and the injured employee became a charge on the law and later on public charity. Bearing this phase of the subject in mind the competent physician would appreciate the necessity of an early return to his accustomed labor by the injured workmen. Discussing the fee bill, the speaker showed that in the past from 50 to 75 per cent. of the cases, taken in the aggregate, did not pay for medical services rendered; of the cases that were paid for by the insurance carrier or the employer most of them went to the contract surgeon, and a tremendous amount of free work was done by the family physician and the hospital. The schedule of charges according to law must be made on an industrial accident basis. It was easy to conceive that the progress of these laws, unless properly safeguarded, might result in the practical enslavement of the medical profession to a bureauocracy created by legislative act. The recent history in European countries bore out this statement. In arriving at the rates decided upon, the commission had considered all the county fee bills that are now in force in the State of New York and from these fee bills and from the fee bill presented by the insurance company the present medical and surgical fee bill was evolved. While this schedule was not adopted, the Commission stated that it would be used as a guide in determining the charges for medical services in disputed cases. It was true that the fees agreed upon for specific surgical operations appeared small and ill-proportioned, when viewed from the heights of surgical eminence, but to the vast majority of surgeons, the certainty of their payment lent to them a delightful attractiveness in the knowledge that formerly they received from this class of patients practically nothing. It was a fact, however, that these rates were higher than those of any of the states in which Workmen's Compensation Laws were in operation. Dr. Boughran considered the objection that had been raised that the cost of rendering medical services was greater in some localities than in others and concluded that there was very little difference made in the charges against workmen in the city and those in the country. The greater difference lay not in the charge made for medical aid but in the amount collected. In this State the Compensation Commission had become voluntarily a collecting agency for all medical bills, and guaranteed the payment of 100 per cent. of doctors' bills when they were rendered in accordance with the spirit of the law. He did not feel that physicians had accepted this bill as the legal profession had done, for it acted everywhere to seriously curtail the income of many lawyers. The legal profession had accepted the act in a spirit of fairness and with a recognition of the humanitarian principles involved. The fact that a bill was reduced did not mean that the integrity of the physician was questioned; it simply meant that the bill had not been rendered in accordance with the law. The charge for first aid was seldom questioned; it was the question of too frequent after dressings. In this respect the practise of different physicians varied considerably. Under ideal

conditions some physicians employed by large corporations had reduced their number of dressings per case treated, taking all things into consideration, to an average of approximately three dressings per case, and this with an infection rate of one in a thousand cases, while ordinarily the number of infections ran one to every ten cases. This demonstrated the danger of too frequent dressings which added to the danger of infection and were an admission that the wound was probably not rendered as aseptic as it should have been to start with.

The Physician's Interests in the Workmen's Compensation Law.—Dr. HENRY S. STARK continued the discussion (see page 561.)

The Legal Aspects of the Workmen's Compensation Law as It Affects the Medical Profession.—GEORGE W. WHITESIDE, Counsel to the Society, presented this phase of the subject. He stated that the Workmen's Compensation Law was, in effect, a scheme of insurance against liability of the employer, created by the Act, for the injury or death of his employee in the course of his employment, against which liability the employer was compelled to take insurance. The Act created for a large class of employees definite rights and for a corresponding class of employers definite and positive duties in respect to those rights, and the purpose of the Act was primarily to provide legal machinery for the enforcement of such employee's rights with adequate safeguards both to employer and employee, against injustice and abuse. What then was the position of the medical man in this situation? It was evident from the discussion thus far that he was not one of the primary factors—he was neither the one for whose benefit the Act primarily created rights, that was the employee, nor the one charged with a duty in respect to those rights, that was the employer. The employee by Section 13 of the Act was entitled under certain circumstances to medical, surgical, or other treatment which required the services of a physician or surgeon. This right in the employee was enforced by placing upon the employer the duty to provide such medical, surgical, or other treatment. This duty of the employer arose only when the right of the employee existed. The physician or surgeon rendering service to such employee did so in reliance upon the right of the employee thereto and the duty of the employer to provide therefor, so that the medical man supplied that to which the employee was entitled and that for which the employer was liable. Obviously the medical man had no standing under the Act unless the employee was entitled to the services which the medical man furnished, so that the medical man's rights in respect to the service furnished by him was based and conditional upon the right of the employee, and the employee's right was the paramount one and the medical man's right conditional and secondary. The Act was not designed or intended as a benefit or a hardship to the medical profession—and its effect on the medical profession is but an incident of its operation and subordinate to the purpose for which it was intended. The interpretation of the Act in every particular, including the aspects that affect the medical profession, therefore, must be in harmony with its general purpose as well as in obedience with its specific terms.

The clause "All fees and other charges for such treatment and services shall be subject to regulation by the Commission as provided in Section 24 of this Chapter and shall be limited to such charges as prevail in the same community for similar treatment of injured persons of a like standard of living" was clearly intended as a protection to the employer or insurance carrier against exorbitant or unusual charges for medical services rendered the employee and provides a limit based upon the prevailing charges in a given community and the standard of living of the injured employee, beyond which limit the employer or insurance carrier should not be liable. When a statute made compulsory upon a certain class of the community to assume definite obligations for the payment of money to their employees under conditions which modify the common law principles of liability of an employer as that has been understood and interpreted, it was necessary to check any abuse possible under such departure from recognized and tried legal principles by safeguards, though such safeguards might occasion to parties other than the employer or employee some hardship or incidental sacrifice. Doubtless the last clause of Section 13, above quoted, might as such safeguard to the employer occasion some hardship or incidental sacrifice to the medical man. The actual disbursement of the award so made was done by the Commission (Section 25) so that a physician's claim under the Act, was secured by a lien backed by the State and was collected through the agency of the State. Thus in the regulation of the relations between the employer and the injured employee, the State in safeguarding those parties had bestowed upon the physician whose claim arises under the Act, the benefits of absolute security. The physician would not be heard to complain of these benefits, but might be heard to object to the amount of his award. In considering the amount awarded for his services he should naturally consider the fact that investments from which the element of risk had been eliminated and the security of which was, in effect, guaranteed by the sovereign power of the State, might give a smaller yield than those of highly speculative character. The physician's investment of his time and talents in the treatment of injured workmen under the Workmen's Compensation Act provided a return that was certain and sure, and if by choice he engaged in this work, accepting the security which it afforded, he might expect for such security somewhat reduced compensation afforded in such cases. Under these circumstances, what schedule should be adopted for regulating the medical man's fees in cases comprehended by the Act? In the twenty-two states now having an Act of this general character on its statute books there was wide diversity concerning the provisions affecting the compensation accorded the medical profession. In the states of Arizona, Kansas, and New Hampshire, the charge for medical services under similar Acts was paid only in the event of the injured man's death and then the maximum paid in Kansas including burial expenses, was limited to $100 and in New Hampshire to $200. In New York State a definite and rather flexible rule was laid down for the gauging of such fees, requiring on the part of the Commission in *each* case, a consideration of the charges for similar treatment, prevailing in that particular community in which the service was rendered and of the standard of living of the person treated. Following the provisions of Section 13 the Commission of necessity could not, with proper respect for the rule there provided, adopt any hard and fast schedule for all cases to be applied in all communities of the State to all persons of varying standards of living. It was plain, therefore, that the so-called fee bill which had agitated the medical profession was not and could not be a schedule fixed by or controlling the commission in its awards for medical service. This was so not only of this fee bill, but also of any other that might be devised that ignored the rules so clearly set forth in section 13 of the act. Mr. Whiteside said that he could not but regard this fee bill as anything other than a starting point from which the Commission in given cases worked, and as such he could see no reason why it could be the subject of serious concern. The question has been asked whether the injured workman must accept, under the Act, the physician provided for him by his employer, or whether he might employ his own physician and have the fees of such physician paid for under the Act. This raised a most important consideration for the medical profession. If the words of Section 13: "The employer shall promptly provide for an injured employee such medical, surgical, or other attendance, etc." were to be interpreted to preclude such employee from employing his own physician at the employer's or insurance carrier's expense, the control of the medical work for injured employees would fast fall in the hands of a few of the large insurance companies and self-insuring corporations, and the cases which otherwise would be distributed among a large number of practitioners would become concentrated in the hands of a few. This issue would probably be raised in some case and its outcome would be a matter of serious interest and influence with the medical profession and should be watched, and, if necessary, some action taken in presenting the medical profession's views to the Commission. In the legal profession the lawyer and his client were recognized as having toward each other a sacred and confidential relationship and the importance and necessity of such personal contact and relationship between the two had often been a matter of judicial consideration. It was regarded as essential. He took it that the medical profession was as jealous, if not more so of its standards and of its rights as any other and that the personal relationship between physician and patient was quite as personal and as sacred as the relationship of attorney and client, and any impairment of the individual's right to select his own physician in whom he had confidence and faith was essentially an

impairment of the personal and confidential relationship between physician and patient. It was of utmost importance that the interests of the medical profession be understood and appreciated by the Workmen's Compensation Commission and that in the consideration by them of the rights of employer and employee under this law the sacred prerogatives and professional standards of a great profession should not be impaired.

After the adjournment of the Scientific Session the Society went into an Executive Session with Dr. E. Eliot Harris in the Chair, and the Committee of the Whole discussed the questions from various standpoints, especially that of the fee bill as set forth in the New York State Medical Journal of August, 1914. By a vote of 63 to 63 it was decided to allow the resolution passed at the November meeting repudiating the bill to stand.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 26, 1915.

Dr. LeRoy Broun in the Chair.

Double Ovarian Inguinal Hernia, Absence of the Uterus, and a Rudimentary Vagina. — Dr. M. Rabinovitz reported this case. He stated that the patient was 35 years of age and had been married six years when she consulted him because of amenorrhea, sterility, and inability to have proper coitus. Physical examination showed that the vagina was represented by a blind pouch, lined with a smooth mucosa, one and one-half to two inches in depth. The introitus vagina was wide enough to admit two fingers, but was lax as if it possessed no sphincter. Vagina-abdominal palpation failed to reveal the presence of either a cervix or a uterus. In each inguinal region, at the site of the external inguinal ring, a semi-solid, irregular, reducible tumor was seen and felt. The right one was the size of a large walnut; the left one was about twice as large as the right, but more cystic in consistency. The reduction of these masses was not complete, for they reappeared as soon as pressure was released, irrespective of the position that the patient assumed. The physical findings furnished the data for diagnosing the case as one of congenital absence of the uterus, a rudimentary vagina, and, in all probability, a double ovarian inguinal hernia. At operation, exploration of the pelvic cavity revealed the following facts: (1) There was complete absence of the uterus. (2) The Fallopian tubes were of fair size, measuring from three to three and one-half inches in length. Their inner ends fused in the median line, forming an ovoid shaped thickening about the size of a lima bean. (3) Both ovaries were well-developed; the left one contained a corpus luteum cyst as large as the right ovary. (4) Both ovaries with part of the fimbriated ends of the tubes protruded through the external inguinal ring, forming the herniæ. Dr. Rabinovitz said that he resected the cystic portion of the left ovary, closed the abdomen, and then performed a bilateral hernioplasty. No attempt was made to improve the existing vaginal tract, since experience with two former cases had taught him that no matter what *modus operandi* he adopted the result would not warrant the additional operative risk, and since until this time the patient's husband had been unaware of her anomaly, having been satisfied with the ureteral orifice which admitted the index finger without causing any pain. The embryological disturbance in this case was an arrest in the development of the lower parts of the Müllerian ducts. The round ligaments were also wanting and were represented by the persistent fetal structures known as "the inguinal ligaments of the Wolfian bodies." This was proven by the fact that the ovaries were resting in the lower ends of the inguinal canals where they seemed to have been held by these embryological remains.

Dr. H. Vineberg said one rarely found the uterus present when the ovaries were absent, and he did not think there was one authentic case reported in the literature where the ovaries, in such cases, had been absent.

Dr. Henry D. Furniss referred to a case of pelvic kidney that occurred in the service of Dr. Ward in which the vagina was found but the uterus was absent. The tubes and ovaries were not discovered in the pelvis and their absence might not have been noted if further and careful search had not been made.

Dr. Rabinovitz said that the case reported was the first one of this nature he had met with and he was, therefore, unable to state how frequently such conditions were associated with pelvic kidney.

The Clinical Significance of Amenorrhea in the Diagnosis of Tubal Pregnancy.—Dr. Rabinovitz presented this report of four cases, giving the history and describing the operation and findings which left no doubt as to the condition being that of tubal pregnancy. Each of these cases demonstrated this clinical fact, that the history of skipping a menstrual period was not an essential diagnostic factor in all cases of tubal gestation. In all the case quoted the symptoms of disturbed gestation set in immediately before or just about the time when the next menstrual period was due, so that the patient could most assuredly state that she did not "skip" a menstrual period. It behooved one, therefore, to keep constantly in mind that irregular uterine bleeding, occurring immediately before or about the expected menstrual period, in conjunction with other well known classical symptoms, was just as strongly suggestive of extra-uterine pregnancy as was the bleeding that took place after the missing of one period. Furthermore, the clinical fact was in absolute harmony with physiological rules; it simply needed a proper interpretation tempered with mature clinical judgment.

Ovarian Cyst with Torsion of the Pedicle in a Child Twelve Years of Age.—Dr. A. H. Harrigan presented this case. The patient had abdominal pain and vomiting four days previous to admission to the hospital; the vomiting was frequent and the pain persistent, quite sharp in character, and more intense in the left iliac fossa. Urination was painful and the bowels were regular. The examination showed a symmetrical abdomen, not distended, but there was rigidity of both recti, more marked in the lower abdomen, and especially on the left side. There was tenderness in both lower quadrants, but particularly on the left side. No mass was palpable. The rectal examination revealed a definite mass in the mid line, movable, situated behind the uterus, and as large as a good sized orange. The temperature was 99.8° and the pulse ranged from 74 to 120; the respirations were 24. The white blood count was 15,000 with 78 per cent. polymorphonuclears. A definite diagnosis was not made but operation was indicated. A mass was found lying between the rectum and the uterus; this was easily delivered and seen to be a cystic tumor the size of an orange. It sprang from the left broad ligament and its pedicle had two complete turns passing from the left to the right. It was black in color and almost gangrenous. The patient made a complete recovery.

Dr. H. M. Vineberg said that four or five years ago he was called to see a girl, nine years of age, on whom he made a diagnosis of appendicitis. She had pain, vomiting, and a high temperature, with a rigid abdomen. There was no difficulty in mapping out a large tumor which proved to be a cyst with a twisted pedicle. It should be borne in mind that young people were not exempt from such conditions.

Early Interstitial Pregnancy.—Dr. Hiram N. Vineberg reported this case which occurred in a woman 32 years of age, the mother of four children, the youngest being three years old. About eight hours before admission to the Har Moriah Hospital the patient had been seized with severe abdominal pain, especially in the right iliac region and radiating to the right shoulder. With the onset of the pain the patient vomited, felt chilly and faint, and was covered with clammy perspiration. On admission it was surmised that an intraperitoneal hemorrhage had taken place, but there was some doubt as the patient gave no history of irregular menstruation, the preceding menstruation having occurred just four weeks before and being regular as to amount and time. The abdomen was distended and markedly rigid, and it was with difficulty that the uterus could be palpated. It appeared to be normal in size and position. The adnexa were not distinctly palpable. A misleading feature of the case was that the patient complained only of agonizing pain between the shoulders and appeared to be free from abdominal pain. The possibility of a ruptured spleen or a perforating gastric ulcer were considered, but the weight of probability seemed to lie in a ruptured tubal pregnancy. At operation the abdomen was found filled with blood. The adnexa on careful examination appeared to be normal on both sides. Owing to the thickness of the abdominal wall and the short broad ligament the uterus could not be brought into view, but there was nothing abnormal about it so far as palpation could determine. The only source for a hemorrhage that

could be found was a ruptured corpus luteum and this seemed insufficient to account for the extensive hemorrhage. Before giving up it was decided to make an ocular inspection of the uterus. The incision was extended and the uterus brought into view and inspected. A small vascular elevation, not as large as a kidney bean, was then found in the right horn of the uterus where the tube entered it. While this elevation was insignificant in appearance, the soft villous tissue protruding from it left no doubt as to its nature. The area was excised and the wound and abdomen sutured in the usual manner, after removing the blood from the peritoneal cavity. The interesting features of this case were: (1) the absence of any irregularity of menstruation; (2) the unusual situation of the pain; (3) the ease with which the source of the hemorrhage could have been overlooked. In a similar case a few years ago, the speaker had seen a gynecologist of considerable experience, after making what he considered a thorough search for the source of the hemorrhage, give it up and close the abdomen. The patient promptly died and at autopsy a condition not unlike that found in this case was discovered. It was the recollection of this incident that prevented Dr. Vineberg from giving up the search until he had inspected the entire uterus.

An Unusual Case of Adenocarcinoma of the Uterus.—Dr. Vineberg presented this report. He stated that the patient, aged 28 years, a widow for three years, entered Mount Sinai Hospital on December 8, 1914. Her family and personal history were negative. About four months ago the menses were prolonged to ten or eleven days. Examination showed the uterus enlarged to the size of the gravid organ at about eight weeks. It lay in retroversion, but was freely movable and easily anteverted. A diagnosis of fibroid growth, probably of the submucous variety, was made. At operation, December 11, it was noticed that the surface of the uterus was slightly rough and presented a deep reddish color. The effort at enucleation was proceeding successfully when a portion of the submucous growth broke down and some grayish friable material presented. A member of the pathological staff who was present suggested that it might be malignant. On closer inspection this supposition seemed well founded and a total hysterectomy was performed. The microscopical examination of the growth showed it to be an adenocarcinoma. The patient made an uneventful recovery. The points of interest in this case were: (1) the early age of the patient; (2) the absence of a flow or discharge in the intervals of the menstrual periods; (3) the evident rapid growth of the tumor; (4) the impossibility of making a correct diagnosis from the symptoms or local findings. This brought up a point in reference to the *x*-ray treatment for fibroid tumors and constituted one of the strong arguments against its universal employment for such growths.

Large Sarcomatous Tumor of Mesentery Removed Together with Eight Inches of Small Intestines; Recovery.—Dr. Vineberg reported this case, which occurred in a woman 29 years of age, the mother of three children, the youngest being two years of age. The patient's history was unimportant until three months before she presented herself to Dr. Vineberg. At that time she took a Turkish bath at the termination of a menstrual period which caused a return of the flow. The two following periods were accompanied with severe pain. The third period was attended with less pain than the two previous ones, but was scanty. Bimanual examination revealed the presence of a tumor lying chiefly to the left of the median line and reaching up midway between the umbilicus and the left rib border. The tumor was movable and cystic for the most part. A diagnosis of cyst of the ovary was made, with probable twisting of the pedicle as evidenced by the recent attacks of pain. At operation the tumor was found to have no connection with the pelvic organs although it lay in part in the cul-de-sac of Douglas and was moderately adherent to the pelvic floor. The tumor was found to arise from the mesentery; it was removed together with the overlying portion of the small intestine which was about eight inches in length. The ends of the intestine were sutured and a lateral anastomosis was made. The abdomen was closed without drainage and the patient made an uneventful recovery. The tumor was the size of an adult's head and proved to be a spindle shaped sarcoma, the center of which showed necrosis, hemorrhage, and cystic formation. The case was interesting because of the comparative freedom from symptoms, the difficulty of diagnosis, and the rarity of the condition. The symptoms of tumor of the mesentery were not characteristic. On local examination they offered one point of differential diagnosis in restricted mobility. This feature was not so marked in the case just reported as to excite due attention and so the plausible diagnosis of ovarian cyst was made for which these tumors were usually mistaken. The rarity of these growths might be inferred from the fact that the speaker in twenty years of active abdominal surgery had never before encountered such a growth. Only 85 cases had been reported in the literature.

Acute Traumatic Displacement of the Uterus.—Dr. Emily Dunning Barringer read this paper in which she stated that trauma had been conceded as a possible cause of uterine displacement, but that in the opinion of most writers it was rare in comparison with other etiological factors. Two reasons for the neglect in recognizing trauma as a factor in the etiology of uterine displacements were: First, that in case of displacement after an accident it was difficult to say whether the displacement had exisited before or not; and, second, it frequently happened that the symptoms were misleading and insidious and hence the condition was overlooked. From the study of a group of these cases the author believed it was possible to consider trauma the direct cause of displacement beyond the question of a doubt and considered a group of six cases which had come under her observation during a period of ten years or more. The histories of the accidents in these cases had shown, as pointed out by other writers, that the violence had occurred, (1) as a result of falls on the back or side in the supine positions, (2) sudden falls in the sitting posture, as falls on the ice, or the hard gymnasium floor, etc., (3) in sudden unexpected strains, where intra-abdominal pressure was enormously increased, or in lifting, pulling, etc. In the series of cases under consideration, a definite history of an injury of the first type was found in two cases, of the second in two cases, of the third type in one case, and in the other case the history was difficult to ascertain as the patient lost consciousness at the time of the accident.

All the cases, on account of their disability, were confined to their homes for periods varying from one week to several months. Five of the cases were nulliparæ at the time of the accident. The symptoms might be well defined or very vague in these cases and the diagnosis might vary from contusions of the coccyx, spinal contusions, "Railway spine," etc., which in no way included the uterus as a possible etiological factor. It seemed to the author that these cases might be recognized if one had in mind the possibility of an acute uterine displacement in cases in which there was present a fairly typical set of symptoms, such as pain over the lower portion of the back, slight sense of nausea and vague distress in the epigastrium when attempting to stand, and a feeling as though "things were out of place." Sometimes the symptoms included a dull ache radiating down the anterior aspect of the thigh, or along the course of the sciatic nerve; sometimes painful defecation; headache, generally occipital; bladder irritability, which sometimes might be a most distressing symptom; and change in the type of menstruation. In one case there was uterine hemorrhage immediately after the accident; in two cases menstruation became painful and prolonged; one case had not menstruated since, and one showed no marked menstrual change. The latter patient had early and successful treatment. There was sometimes a characteristic posture and gait very similar to that of traumatic lumbago, so marked that it might be noted on meeting the patient. The lower abdominal muscles were more or less contracted. In sitting the patient avoided direct pressure on the coccygeal region. In these cases vaginal examination showed various degrees of retroversion.

The author's cases showed three types, the mechanism of which the author described, comparing the uterus in its setting to a perfect joint and the accidents to dislocations of a joint. The result of any of these dislocations was to put certain of the uterine ligaments on the stretch and in certain extreme instances to actually tear the ligaments as in a dislocation of a bony articulation. A study of the mechanism of these displacements easily explained the symptoms of displacement. In cases of this class the importance of an early diagnosis was very great on account of the subsequent congestion and further sequelæ. The reduction soon after the accident was easy as a rule, and probably best effected in the knee-chest position. The uterus would sometimes "snap" back

into place and remain there and all discomfort immediately cease. This was demonstrated in one of the cases in which the diagnosis was made a day or so after the accident, and in which complete recovery followed rest in bed on the abdomen for a week and avoidance of exercises involving a concussion, such as horseback riding. This patient was advised to continue swimming and gradually resumed a vigorous athletic life. She had since married and become pregnant and had no difficulty with the pregnant uterus. When the uterus had remained out of position for a week or more the congestion incident to trauma made the reduction more difficult, and it then became necessary often to tampon the posterior fornix and between treatments use prolonged hot douching. Early diagnosis in these cases usually meant complete cure, while the longer the period of displacement, the less the chance of a non-operative recovery. It was important to arrive at a correct diagnosis because of the legal aspect of these cases. In four of the six cases reported the diagnosis had been overlooked and in two a rectal or vaginal examination had not been made. It should be made an invariable rule that the pelvic organs should be carefully examined in all cases of accident before one should make a diagnosis of railway spine, traumatic lumbago, concussion of the spine, traumatic hysteria, etc.

Dr. Hermann Grad said that these traumatic displacements were rather rare and when a retroversion was encountered it was difficult to say that the displacement occurred at any particular time. Dr. Marion Syms was the first to call attention to traumatic displacement of the uterus and the observation of that case led him to the invention of the Sym's speculum; by the use of this instrument he raised the posterior wall of the vagina; air would then enter and assist in the reduction of the displacement of the uterus. Two important points pertained to the condition of the bladder and to the condition of the perinuem at the time of the injury. If the bladder was distended at the time of the accident, it would push the fundus of the uterus toward the sacrum and one could readily see how under these conditions intra-abdominal pressure would become a factor in the uterine displacement. Again, whenever the intra-abdominal pressure was increased, like coughing or sneezing, the perineal musicle contracted automatically and gave support to the pelvic floor and the contents of the pelvis. During traumatism these synchronous muscular actions did not take place and, therefore, Dr. Grad said, their actions were not effective factors in preventing dislocations of the pelvic organs.

Dr. Abraham J. Rongy said that the symptoms which might be due to a traumatic displacement of the uterus were subjective in nature and the physician had no means of ascertaining the validity of these complaints. Personally he believed that the diagnosis of traumatic displacement of the uterus should never be made unless the patient had been examined before the accident and a change in the position was discovered immediately following the accident. Simple displacement of the uterus seldom caused symptoms. Dr. Rongy said he would be unwilling to ascribe any form of acute displacement of the uterus to an accident unless the latter was accompanied by a severe pelvic injury.

Dr. Barringer said that she had not intended to imply that she had made a physical examination in these cases before the time of injury, but had relied upon a careful history of the accident and physical findings after the accident. She believed that her cases had been in good health as regards the pelvic organs before the accident, and afterwards they were not. Two of the cases had previously been patients and had never complained of pelvic trouble. Both of these cases were completely disabled immediately after the accident. To consider all uterine displacements as being due to external trauma was absurd, as the vast majority of uterine displacements arose from other causes. In the course of ten or twelve years, in examining accident cases, she had found many cases of retroversion and prolapse which she had not reported as traumatic in origin. She supposed the three medicolegal cases reported in her series had been found in the course of about 150 such medicolegal examinations. Dr. Barringer said that she was much interested in these cases and realized that because of the element of litigation it was difficult to study them and obtain correct statistics.

College of Physicians of Philadelphia.

At a stated meeting held March 3 Dr. Alfred Reginald Allen presented a communication entitled "Recent Progress in the Physiology of the Pituitary Body." With the aid of lantern slides Dr. Allen discussed and illustrated the embryology, the histology, the anatomy, and the functional activity of the hypophysis. He showed how by reason of the complexity of the structure of this gland disease in one part might be unassociated with disease in an adjacent part, and how hyperplastic processes, with perhaps increased functional activity, in one lobe might be associated with disorganization of another lobe as a result of pressure with diminished or abolished functional activity. In this way were to be explained the multiformity and the contrariety in the symptomatology of disorder or disease of this organ. The anterior portion of the hypophysis appeared to have to do especially with tissue-growth and the posterior portion with carbohydrate metabolism.

Dr. George E. de Schweinitz read a paper entitled "Visual Phenomena in Disorders of the Pituitary Body." He pointed out that as a result of pressure on the optic tracts, chiasm on nerve vision might be impaired in any degree in the presence of a new growth involving the hypophysis, from mere obscurity to total blindness. Various forms of hemianopsia, homonymous and heteronymous, observed, with peculiar central scotomas, together with changes in the fields for form and color.

Dr. Charles H. Frazier presented a communication entitled "Clinical Manifestations of Pituitary Disorders in their Relation to Surgical Therapy." The principal symptoms for which patients suffering from disease of the hypophysis came under observation were headache and disorder of vision. In rare instances relief had been obtained from organotherapy, but as a rule not much was to be expected from this source. Usually the most that could be done was to perform cerebral decompression for amelioration of headache and conservation of eyesight, but at times successful removal of the neoplastic or hyperplastic formation could be effected. In some cases this could be done by the transfrontal route, while in others the transsphenoidal route was to be preferred.

Dr. Lyndon H. Landon by invitation read a paper entitled "The Transsphenoidal Approach to the Sella Turcica." He described the operation in detail, pointing out its advantages over other procedures directed to the same end, as well as the precautions to be observed in its performance. The steps of the operation as well as some of the conditions found were illustrated by lantern slides.

The Excretion of Arsenic in the Urine Following Use of Salvarsan.—K. Irokawa finds that from 40 to 90 per cent. of the arsenic injected either subcutaneously or intravenously is excreted in the urine during a long period of time. If salvarsan is injected subcutaneously it remains at the site of the injection unabsorbed and one can detect arsenic in the urine, after the lapse of three weeks. Excretion of arsenic following the intravenous injection is also quite slow. In a relatively large number of cases a fairly large quantity (10 per cent.) of the arsenic is excreted during the first day, but the greater part of the arsenic is excreted in the course of the first week. Even in the cases in which repeated injections have been performed intravenously a large quantity of the arsenic is not excreted during the first day. The relation between the excretion of the arsenic and the symptoms of syphilis is difficult to determine, but it has frequently been observed that the symptoms improve when the arsenic excretion is marked and get worse when the excretion is diminished.—*Sci-i-Kwai Medical Jornal.*

Hypertrophied and Dilated Urinary Bladder.—C. R. Box reports the case of a male, aged seven years, whose abdomen was noticed to be of an odd shape three weeks after birth. About this time the boy was circumcised. At the present the urinary bladder is greatly hypertrophied and dilated; it reaches almost to the navel. The child does not empty it completely and has some difficulty in starting micturition; nocturnal enuresis is present. There is polyuria (40 ounces or more in twenty-four hours). The urine varies in specific gravity from 1,004 to 1,030; it contains a trace of albumin but no casts. The point of special interest is the great hypertrophy of the bladder without any obvious obstruction of the urethra. Skiagrams show no stone; a catheter passes easily, and per rectum only the large bladder can be felt.—*Proceedings of the Royal Society of Medicine.*

THE TREATMENT OF DIABETES MELLITUS IN DISPENSARIES.

BY HERMAN O. MOSENTHAL, M.D.,

BALTIMORE, MD.

ON account of the large amount of time that has to be spent upon each patient to obtain good therapeutic results, the treatment of many diseases, among them Diabetes Mellitus, in dispensary and office practice is extremely unsatisfactory. In order to obviate this difficulty, the following scheme was developed at the Vanderbilt Clinic in New York City; it was thoroughly tried out over a period of more than three years, and was found to yield good results. Three main objects were kept in mind. These with the methods of their accomplishment were as follows:

1. *The education of physicians wishing to acquire a knowledge of the disease.* This need is a greater one than is generally realized. Many practitioners have a very inadequate conception of the proper treatment of diabetes mellitus. An opportunity for remedying their deficiencies is not at hand, and they struggle along as well as they can. Men actively engaged in the practice of medicine are unwilling to spend three afternoons a week in studying and treating a single disease. Therefore, the presence of clinical assistants was asked for on only one day a week. This scheme was productive of admirable results, as long as the number of patients treated was within the working capacity of the clinic. The latter object was readily accomplished by having the cases return by appointment only. In this way, a group of from four to six physicians observed approximately sixty cases of diabetes—an ample amount of material for clinical experience—and the cases could be kept under thorough control and be furnished with proper treatment. By means of a uniform record system, each doctor was enabled to understand his predecessor's method of procedure and build upon it, without more than a minute or two spent in studying the history sheets. Thus every physician in attendance sooner or later came into contact with the whole clinical material, without detriment to any of the patients.

2. *Provision for adequate statistical and teaching material.* This need applies more to University Clinics than it does to the out-patient departments of hospitals. That a "diabetic" or, considered from a broader point of view, a "metabolism" clinic, fills a great want in this regard, is self-evident. For the completeness of clinical data and thoroughness of therapeusis, it is of great advantage if recourse may be had to an affiliated hospital for the treatment of the more serious cases and those burdened with complications. For three years the Vanderbilt Metabolism Clinic has furnished material for systematic instruction, bringing before the student the picture of the disease from the incipient to the advanced stage, and from the mildest to the severest type, in an orderly fashion.

3. *The adequate treatment of patients.* This is the keystone upon which the success of the clinic rests. The rule that each patient shall appear by appointment only must be strictly adhered to. If four physicians are in attendance, and each one can handle approximately four patients in two hours, it would be feasible to allow for twelve visits of old cases and leave one assistant free to interview the newcomers. Under such a system the patient requiring attention once a week receives it, while mild cases may be seen only once in two months; this meets all the necessities of the patient, without wasting the time of the medical staff. One further point requires emphasis: When the clinic is running to its full capacity admission should be refused to new cases. This is a matter of very great importance, and yet it is not put into force in any outpatient department, so far as the writer knows. Hospital authorities have put such a rule into effect for the wards, but not for the dispensaries. In an overcrowded clinic proper attention to each applicant is impossible, and either quantity or quality of therapy must suffer. In the metabolism division of the Vanderbilt Clinic there was frequently a waiting list, and, though this was unfortunate, it tended toward the greatest good of the greatest number. A patient, on being admitted to the clinic, has his admission history and physical examination charted upon the following blank:

Such a "standardized" history appears at first sight to have many disadvantages, the main one being, that it does away with all incentive to original thought on the part of the observer. This is true to a certain extent, but may be counterbalanced by leaving enough blank space for such observations. The advantages, on the other hand, are very many. These history blanks are complete, and present the facts in a definite order. Through them statistics may be obtained concerning heredity, etiology, etc., with a minimum effort. Before this scheme was put into force, any statistical compilations which were attempted resulted in failure. It was found that the histories, even when taken carefully and conscientiously by competent workers, were full of omissions and it required much energy and time to read through pages of script to become oriented. With the present scheme, no such difficulties are encountered. It also makes the separate visits of the patient much more interesting to the physician, as any desired details may be rapidly ascertained without the usual series of wearisome questions.

The diet lists employed in this work are similar to those generally accepted in the treatment of diabetes mellitus, and the principles guiding their use differ in no way from that set down in the recent treatises concerning the disease. Their main merit is in being concise and clear, and thus leaving no doubt in the patient's mind as to what is required. Many of the Jewish cases refuse to eat the bacon demanded on the green day diets. A list was, therefore, devised in which beef flank, which has a very high fat content and is inexpensive, was substituted for bacon. This was found to answer very well. The restricted protein diet presented insurmountable difficulties. Up to the present time, no feasible plan has been developed by which a diet requiring weighing can be successfully maintained by a dispensary clientele.

VANDERBILT CLINIC
Amsterdam Avenue and 60th Street
New York City

Starch-free Diet.

MAY EAT:
Soups—Clear meat broths.
Meats—All kinds of meat, fresh, smoked or cured, except liver; all meats must be prepared without flour or breadcrumbs.
Eggs—Eggs in any form, prepared without milk, flour or sweetening (sugar, jam, etc.).
Butter—Butter, oil and lard.
Cheese—All kinds of cheese.
Fish—All kinds of fish, but no clams, oysters or scallops.
Vegetables—Greens, spinach, string beans, Brussels sprouts, asparagus, lettuce, endive, cucumbers, celery, cabbage, mushrooms, tomatoes, sour pickles.
Desserts—Gelatine jellies (use sour white wine, brandy or coffee for flavoring), custards made with cream only (without milk), and sweetened with saccharine (do not use sugar).
Beverages—Tea and coffee, sweetened with saccharine (without sugar or milk); claret, burgundy, sour white wine, and whiskey in moderate amounts. Vichy and water. Thick cream, 4 ounces (½ tumbler) a day, to be used with tea or coffee, or as desired in cooking.
Condiments—Pepper, salt, mustard, oil, vinegar.

MUST AVOID EATING:
Sugar in any form. Bread, biscuits and cakes of all kinds. Toast, crackers, rice, oatmeal (and all cereals); sago, tapioca, macaroni, vermicelli, potatoes, carrots, parsnip, beets, corn, beans, peas. All fruits, fresh, preserved and dried. Jams and jellies. Pastry, puddings and ice cream. Sauces and gravies thickened with flour.

MUST AVOID DRINKING:
Milk, ales, porter, stout, beer, cider, all sweet wines, port wine, liqueurs, sparkling wines, syrups.

BESIDES ABOVE, MUST EAT:

Green Day with Bacon.

BREAKFAST:
1 egg, boiled or poached.
Cup of black coffee.

DINNER:
Spinach with a hard boiled egg.
1 slice of bacon (this should weigh ½ ounce)
Salad, with 1 tablespoonful of oil.
¾ of a water glassful of sour white wine, or claret, or 2 tablespoonfuls of whiskey or brandy.

4.30 P. M.
Cup of chicken broth.

SUPPER:
1 egg, scrambled, with tomato and a little butter.
1 slice of bacon (this should weigh ½ ounce).
Cabbage, sauerkraut, string beans or asparagus, canned or fresh, in any quantity desired.
Cup of tea, without milk, sugar or lemon.

Take three flat teaspoonfuls of bicarbonate of soda during the day.

Water may be taken as desired.

Green Day without Bacon.

BREAKFAST:
1 egg, boiled or poached.
Cup of black coffee.

DINNER:
Spinach with a hard boiled egg.
1 slice of beef flank (this should weigh 1 ounce).
Salad, with 1 tablespoonful of oil.
¾ of a water glassful of sour white wine, or claret, or 2 tablespoonfuls of whiskey or brandy.

4.30 P. M.
Cup of chicken broth.

SUPPER:
1 egg, scrambled, with tomato and a little butter.
1 slice of beef flank (this should weigh one ounce).
Cabbage, sauerkraut, string beans or asparagus, canned or fresh, in any quantity desired.
Cup of tea, without milk, sugar or lemon.

Take three flat teaspoonfuls of bicarbonate of soda during the day.

Water may be taken as desired.

Oatmeal Day.

8 ounces (½ lb.) oatmeal.
8 ounces (½ lb.) butter.
6 eggs.

Cook the oatmeal thoroughly in water for 2 hours.
The butter and eggs must be well stirred in when the oatmeal is nearly done.
Use salt as desired.
This constitutes the food for one day. It may be eaten as gruel, mush or fried mush. It should be divided into 7 equal parts, one part to be taken every 2 hours.
Two cups of black coffee, and ¾ of a water glassful of sour white wine or claret, or two tablespoonfuls of whiskey or brandy may be taken throughout the day.

A patient on applying at the clinic for treatment is questioned and examined, and the observations are charted upon the history and physical examination blank. Dietary directions are then given. The diet usually ordered consists of the starch-free list, with some extra starchy food, such as three Uneeda biscuits with each meal, a slice of bread with each meal, or either of the above with an orange or an apple, etc. Each case is treated individually, and allowances are made for acidosis, idiosyncracies and personal preferences, and the dietary directions varied as indicated. The patient is told how to collect and measure a twenty-four-hour specimen of urine, is given one of the slips on which to chart all food and fluid taken during the period of collecting the urine, and is told on what day to return. At the subsequent visit, some errors are usually detected in the patient's "technique." The blank which has been filled out is a great help in this connection.

Metabolism Clinic

Diet List for M.....
For the day.....19

(Specify every article eaten as well as giving approximate amounts, as: 7.30 A. M., Breakfast—1 cup of coffee, bacon 2 slices, 1 egg, water 1 glass, etc. Give time of each meal. Mention all food taken between meals.)

BREAKFAST:

LUNCH:

DINNER:

It enables the physician to tell whether the patient is eating a sufficient quantity of food, whether the diet as prescribed is fully understood, and, at times, helps in the detection of secret infringements of the prescribed diet. In treating diabetes, the medical advisor is in the fortunate position of knowing how strictly his patient is adhering to the dietary directions. A urine containing much sugar and no acetone is not that of a man on a strictly carbohydrate-free diet, no matter what his statements on the subject may be. The urinary analyses are best made before the patients themselves. Only a small laboratory equipment is required, and this can be placed in the clinic room without inconvenience. Dispensary cases are so frequently told that their urinary examinations will have to be postponed, obviously because the physician is either too busy or otherwise preoccupied, that an analysis of the urine in their presence has a very great effect in winning the confidence of the patients. It also saves the doctor's time by enabling him to do all his work within a short radius of space and to talk with the patient while he is working. The labora-

*C. F. is an abbreviation for Carbohydrate Free.

tory equipment should include the following: Means for determining the reaction of the urine, the specific gravity, albuminuria, the qualitative and quantitative* glucose reactions, the presence or absence of acetone (Legal's reaction) and diacetic acid (Gerhardt's test). If access can be had to a centrifuge and microscope and the apparatus necessary to make blood sugar, ammonia, nitrogen and acid body determinations, the interest and pleasure in the work may be greatly increased, though these instruments are not absolutely essential. The urine having been analyzed, the patient is weighed, and a physical examination is made, if necessary. A sample of one of the combined urine and daily note charts is given.

These charts measure 21 x 9¾ inches. When folded over twice, they conform in size to the regular dispensary histories and can be filed with them. Nineteen columns are provided for tabulated observations. Of these, only the ones for the date, urinary volume, specific gravity and reaction have printed headings; the remainder are inserted according to the exigencies of the case and the desires of the observer. The appended sample is from one of the simpler cases. On the right is a blank space on which the diet is charted and the daily notes recorded. By this method, all the data of each visit are written on one line and are ready for rapid and complete inspection at each following consultation. The severest cases requiring more intensive treatment are referred to a hospital, and are asked to return to the clinic subsequently. Of almost 300 cases handled in this way, there was not one that was not benefited to some degree; in many the best therapeutic results could not be obtained, in some instances because of lack of will-power, in others because of lack of money to keep up an expensive dietary regimen. The Social Service department proved of inestimable value in meeting these emergencies.

The Johns Hopkins Hospital.

NEURASTHENIA AMONG GARMENT WORKERS.

By VALENTINE C. BAKER, M.D.

NEW YORK.

ASSISTANT PHYSICIAN OF CORNELL UNIVERSITY MEDICAL COLLEGE DISPENSARY; SHELDON FELLOW IN MEDICINE.

At the suggestion of Dr. W. Gilman Thompson, I undertook the investigation of neurasthenia among garment workers. In 1910 there were about 60,000 people employed at this trade in New York City, showing the industry to be a very important one.

The process of manufacture may be divided into three parts: the cutting, the sewing, and the pressing procedures. The cutting process consists in having a number of layers of cloth on top of which is placed the pattern, and the cutting of the goods, which is accomplished by means of shears, a large knife or the modern circular knife, operated by a small motor and guided by the operator. This work is performed by experts who command good wages and usually are paid by the week. Their work is more regular than that of the other departments. They are also given more space and as more light is required, are placed in the well lighted positions of the shop.

The sewing is one in which the work is specialized. Each worker is employed in basting, hand or machine sewing, on just one special portion of the garment.

The basting, requiring but little skill, is done by the beginners. The machine operators then finish the garment. The machines are usually in long rows set on tops of tables. The motive power is usually by electric power, but may be by foot.

During the assembling of the garment it is sent to the pressers. This work is done by hand-iron or heavy irons worked by hand or foot. The irons are heated by coal stoves, gas stoves, gas heating attachments to the irons, and electricity. The presence of carbon monoxide and an excess of carbon dioxide and aqueous vapor is the result.

Turning from the process of manufacture to the seasons, one is at once struck by the irregularity of the work, the rush and the slack seasons. Of the rush seasons there are two, known as the winter, August 15 to November 15, and the summer season, January 15 to April 15. These dates are approximate, varying somewhat with the nature of the garment and fashions. There are then about 4 to 6 months in which a man can work at his trade and draw the best wages. Dr. George M. Price tells me that if the wage earning capacity was reckoned on the daily average at this time, it would show that the worker is getting only 40 to 50 per cent. returns on his earning ability, at best. It would seem that these figures would be too high for the majority.

What happens in the slack season? There is very little work in the shops at times, 2 to 3 hours per day to none at all. The workers report at the shops and do what work there is.

Some find other work for the slack season in small stores and by peddling. The number of workers is increased in the rush season by some who have other business, which they leave to make more money while the returns are high.

The annual report of the Joint Board of Sanitary Control in the Cloak, Suit, and Skirt Industries, New York, 1913, shows the location of the shops to be as follows: In lofts, 83.8 per cent, while the number of shops in stores, attics, and cellars have decreased. This improvement is most satisfactory, for the loft is a more modern and hygienic location. Most of these places lack a separate lunch-room and dressing facilities. According to the report, these conditions are being remedied.

Taking the medium sized shop for an average example, one finds a fairly large room in which all the processes of manufacture of garments are going on. The cutter stands at his table under an arc light, a bright glaring light, or near the windows. On the floor at his feet are many small pieces of cloth, getting finer and finer as he walks around at his work. In better organized shops the pieces are kept cleaned up and placed in a tin-lined and covered receptacle.

At another portion of the loft are long rows of benches, on which are placed the machines, the shaft propeller protected usually by a board, which is only a fair protection for women's skirts. These machines are lighted in various ways, most are placed so that plenty of daylight is present. Others are lighted by electricity, most of these lights being shaded. Some shops used gas jets above the machines, protected by a wire shield. Some of these lights were formerly not protected and were a constant source of fire-danger as the busy worker flung the garment around in his haste. None of these

*Benedict's modification of Fehling's method has rendered excellent service. Benedict, S. R., *Journal of the American Medical Association*, 1911, LVII, 1193.

were shaded, not to mention the amount of air consumed and contaminated with carbon dioxide and other products of the complete and partial combustion of illuminating gas.

The chairs and benches are usually of the proper proportions, but I have seen some in which an average size person's knees must have been well on the way upward to his chin.

The workers sit at the machines, bent forward with their faces from 6 to 12 inches from their work. Their backs are bent in a quarter circle, an entirely unnecessary position with the chairs and lights used.

The pieces of work are small or large, according to the nearness of completion and the nature of the article. When finished these are dropped into baskets or other receptacles to be carried to the pressers.

These pressers were grouped in another part of the shop. They used mostly gas irons, fitted with air pressure, which insured the complete combustion of the gas and less contaminated air. However, there were many using the old gas irons. In none of the shops visited were there any hoods or other means to carry off the air about the irons. Also the pressing department was not separated.

The middle of the shop is commonly used for storage purposes. No dressing or lunch rooms were provided in those places visited. The toilets were fairly adequate in number, but the entrances were not screened off.

The report of the New York Bureau of Factory Inspection, 1911, concerning ventilation, showed that a large loft with numerous windows was not necessarily well ventilated. It was found that different portions of the loft varied greatly in the amount of carbon dioxide, solid matter, and the number of bacteria present. The presence of gas heating irons produced considerable carbon monoxide. There was also a large amount of dust, although the trade is not considered a dusty one. These findings would call for greater cleanliness and an efficient method of ventilation, preferably one in which the air is washed before distribution. In the case of gas irons mechanical means should remove the carbon monoxide and furnish fresh air. The gas and air apparatus causes a more complete combustion and obviates to a certain extent other means. Electric irons are good, but more expensive. The proper ventilation by means of open windows would vary with the seasons and individual preferment, which is a fallible safeguard.

In addition to the ordinary dust there is added the fine particles of material ground by the shoes of the workers as they walk over the scrap pieces. Proper cleanliness would remove this factor. In the shops visited, although not very busy, this material gathered rapidly. Otherwise, as to cleanliness, the shops were fair to good.

The means of entrance are by stairs and elevators. There is no necessity for the use of stairs. However, the elevator is small in many places and would require long waiting in rush periods.

In going over the great number of garment workers sent to the Cornell Medical Clinic for treatment by the United States Public Health Service, the presence of a neurotic element was apparent in the majority of the patients where the symptoms were in great excess to the physical signs. The most common symptoms were: exaggeration of symptoms, painful spines, indefinite pains variously located, mental depression, discouragement, and worry. Practically all the patients were Jewish and of Russian birth. This type of persons is noted for the occurrence of nervous diseases.

The following 18 cases were selected for statistics, because of the absence of organic diseases: Neurasthenia, 6 cases; neurasthenic spines, 4 cases; neurasthenia with gastric neuroses, 2 cases; nervous headaches, 2 cases; mucous colitis, 1 case; neurasthenia with obesity, 1 case; sexual neurasthenia, 2 cases.

Of these patients it was found that 3 were born in the United States, the other 15 were born in Russia. Two were of German descent and the remainder were Jewish. The sexes were 14 males and 4 females. As to civil condition, 13 were single and 5 married. The ages varied from 16 to 37 years, the average being 24 years.

The former occupations were as follows: School work, 6; farming, 1; fur trade, 1; examining embroidery, 1, and tailoring, 9.

The length of time at the garment trade varied from 6 months to 23 years. The 23 years' duration was that of a patient aged 37 years. One patient had left the trade and become a bookkeeper in the garment shop. Two patients were spending their evenings at night school.

In only 2 cases was the work regular. In the rush season there was plenty and in the slack season a small amount to none at all, 6 months of the year being spent in doing what little work there was to be found.

The kinds of work at which the patients were employed were as follows: Pressing, 1 case; hand sewing, 4 cases; machine operating, 13 cases. Thirteen patients did piece work and in all but 3 there was a "speeding up" of work, especially in the rush seasons, and by the employees to increase their wages.

One of the most important factors is the position of the workers. All the machine operators sit at their work, as do the hand-sewers. They bend forward with their eyes near their work. This bending forward seems to me to account for many of the spinal and other body pains.

The hours of work per week varied from 50 to 70 hours in one case, 13 working during the rush season about 50 hours. The figures given are for the rush season. During the slack season they may work a few hours, when a little work comes in, to none at all.

As to the place of employment, 17 worked in loft buildings. The other patient worked in a tenement. The work-room was described as large in 15 cases, and small in 3. Overcrowding was complained of by 5 patients. This seems to occur most often at the rush season. In reaching the shops 4 patients were obliged to use the stairs, which varied in number of flights from 1 to 6.

Ventilation was obtained by means of opening the windows in all but one shop, in which mechanical means were used. This simple way of ventilation is very faulty, the pure air being unevenly distributed. In the cold weather there is closing of the windows. This was complained of especially by the girls, who said that some of their number were always closing the windows.

The method of heating, being by steam, was satisfactory in all cases. However, there was no way to tell at what temperature the rooms were kept or if the heating was evenly distributed.

As to the presence of gas-heating irons, it was found that these were used in the same room in 13

instances. No separate room was provided nor were there hoods or other mechanical devices to carry off the products of their combustion. The use of gas and air pressure is providing a more complete oxidation of the gas.

The lighting was by daylight and electricity in all 18 cases closely studied. Shades were used in all but 4 cases. If these were shaded as poorly as some seen in the shops visited, in which large electric lights were equipped with shades several sizes too small, allowing the glaring light to shine directly in the eyes, these shades were of little use. The cases investigated all had day and electric lights, but several of the shops visited used gas light, with which there were no shades.

The time given to lunch varied from ½ to 1 hour. One man took no lunch-hour and he was suffering from a gastric neurosis. In no case was there a lunch-room provided. Three of the women and two of the men ate their lunch in the work room, the others eating at a restaurant. The lunches described were extremely satisfactory.

The distance that the patients lived from their work varied from ½ to 8 miles, 13 being within 1¾ miles, the remainder living at a much greater distance. In reaching their work 3 patients walked; the others riding on the surface, elevated or subway cars as suited their purpose.

In their salaries the women's varied from $5 to $7 per week, and the men's from $10 to $32 per week. These figures were taken for the rush season. When it is considered that the worker can possibly make only 40 per cent. of what his wages would be if his work were regular, we can approximate his yearly earnings; for the $10 per week man, $200 or less, and for the $30 per week man, $625 at best. One can appreciate what the high cost of living means to them.

The occurrence of similar disease conditions in co-workers was given as negative except in 2 instances, where several were said to complain of headaches and backaches.

In investigating the home life of the cases cited, it was found that 2 were attending night school. Also 2 of the girls helped with the housework. The sleeping quarters consisted of an inside bedroom in 6 cases, the remainder having windows that opened on the outside. At night the windows were kept open in all instances; 2 only in summer, and one only a little, in winter. In 5 instances the bedrooms were occupied alone, while there were 2 or more occupants in the remaining 13 cases.

The social lift included parties, theaters, and motion pictures. As to exercise, 1 girl belonged to a gymnasium, another patient was a bicycle rider. The others took their exercise in walking. Thus we see that in only 1 case was there systematic exercising.

The family history in 3 cases stated the mother to be neurotic. In one of these instances the mother was insane. This fact is of interest in that inherited tendencies are claimed to be transmitted through the mother.

The illness in all but 2 cases developed during their employment in the garment industry. Of these two, one began to have "nervous trouble" in childhood and the other dates her illness from the time she started to work. The duration of illness was 6 years in 2 cases, 4 years in 5 cases, 2 years in 8 cases, 1 year in 1 case, 6 months in 1 case. These figures show that, at least, the disease developed during their present employment.

Dr. Sidney Schwab reports in the American Labor Legislation Review on "Neurasthenia in Garment Workers" that he found that among laborers, laundry workers, workers in metals, and out of doors, neurasthenia was rare, while in 25 to 30 per cent. of garment workers neurasthenia was present. This has been practically our experience in the Cornell University Medical College Dispensary.

He considered the following to be factors in the occurrence of neurasthenia among garment workers: The majority of the workers being Russian Jews, the irregularity of the work with the speeding up at the rush seasons, the overtime, the out of work with worry and anxiety, and the piece work, which is monotonous and varies in amount and the wage earned.

Our findings agree with his to a great extent. Practically all the workers were Russian Jews, a type of people especially subject to nervous complaints. In only 1 case was the former occupation given as farming. The majority had been tailors or in allied trades. So one considers they should be to a certain extent adapted to their labors.

The irregularity of the work is an important factor. The rush to make all the wages possible during the busy season puts a heavy strain on both muscle and mind. This causes a general fatigue. Then comes the slack season, with its diminished wages and attendant worry and anxiety.

The remedy for this will be hard to secure, as it is naturally a result of climatic and other conditions. Perhaps in time the work can be planned ahead so as to provide continuous labor for the employee, and remove the expenses of a building idle for 6 months of the year from the employer. Economic reasons will aid. Efficiency in both the work and the worker is being investigated and utilized by the up-to-date manufacturer. It has been shown that a steady business is better than an irregular one for all concerned.

As to piece work, which has a tendency to become tiresome and monotonous, we find that it puts considerable strain on the worker in his endeavor to make the most possible. There is the lowering of the wage for each piece, attended by the increased amount of work necessary to make a sufficient salary. In New York it has been suggested that the work of an average worker be taken for the fixed scale of pay and not that of the expert. This seems to be a very good idea, thus giving the individual a chance to profit by his industry.

The position of the worker has already been commented on in this paper. Attention to the same by the worker would help. Light exercise at home or a gymnasium would relax and relieve the cramped muscles.

In the home life better tenement conditions will remedy these factors. The outside bedrooms should be the rule and not the exception. The importance of an undisturbed sleep to the worker can easily be recognized. Two occupants to a room would seem to be a suitable limit. The hours spent in bed were given as 7 to 8. Social meeting places in the neighborhood would act as a diversion.

As to family history, we can only look forward to the placing of the feeble minded and markedly neurotic in institutions where the occurrence of descendants will be prevented.

The Joint Board of Sanitary Control in the garment industry, the employer, the unions, and labor legislation are doing much to better the conditions

by inspections, suggestions, cooperation and suitable laws and regulations. These endeavors have produced satisfactory results in the past few years.

Perhaps it would not do to draw too decided conclusions from the small number of cases cited, but it seems from general dispensary work that neurasthenia is probably no more prevalent among the Russian Jew of the garment-shop, than the Russian Jew of any other occupation. The percentage of neurasthenia is always high among this race. Another factor is the rush and slack seasons, with their strain and fatigue, but only as an excitant of an already present neurotic element. Thirdly, piece work, in which there is the endeavor to earn as much as possible, holds about the same position as a causative factor as the seasons. The position at work seems the chief factor in the body pains, and neurasthenic spines. Instructions in proper positions and exercise at home or in the gymnasiums would correct this cause. Other causes, such as improper lighting and overcrowding, are well covered in New York by laws and inspections.

The conclusions as to symptoms peculiar to the trade showed only one, the painful spines, to be prevalent. The occurrence of other symptoms, such as anemia, constipation, eyestrain, decreased chest expansion, and permanent deformities, were not strikingly prominent features. One girl had a lateral curvature of the spine, which was present before she became a garment worker. The others were negative as to deformity. The garment-trade seems a fairly well regulated and sanitary trade in New York City, and compares favorably with other trades in these factors. The tenement shops and home work are the objectionable features. However, the number of workers employed in these shops is very small. The Joint Board of Sanitary Control, composed of employers and employees, has and is doing much to better conditions, for which it should be given due credit.

In closing I wish to thank Dr. W. Gilman Thompson, Dr. George M. Price, Dr. William H. Sheldon, and others who have aided in my work.

664 West One Hundred and Seventy-ninth Street.

THE INFLUENCE OF THE STUDY OF MEDICINE ON RABELAIS.*

By DOUGLASS W. MONTGOMERY, M.D.,
San Francisco, Cal.

Rabelais had the rare faculty of being able to work into his writings what he personally observed. In other words he was a most clever realist. As we are apt to think of him as the creator of characters of a most unreal bigness, this estimate of him may seem strange. As Abel Lefranc, however, says, the proofs of this side of Rabelais' way of constructing his stories have so accumulated during the last ten years that our conception of him as a writer has become profoundly modified.[1] It is known definitely that he practised medicine and that he had charge of a hospital, and in a man of his realistic type of mind these facts alone account for page after page of his works giving scenes and incidents having a decidedly medical flavor.

There are at least two classes of medical observations in Rabelais' works. In the first place there are his direct medical statements. These give some idea of medical thought and practice in the Middle Ages. They are curious and interesting in an antiquarian sense, but, of course, very little can be learned from them, as all the sciences on which the practice of medicine, as we understand it now, rests were then only either in their infancy or not at all imagined as existing. The other class includes medical turns of thought and ways of observing human beings, made by a master in his art. As human nature does not change, these are as fresh and true now as on the day they were written. It is here also that some of the finest examples of his realism may be found. As being made by a medical man of first class literary ability these observations are peculiarly precious to medical men. They show delightful pictures of the human side of medicine that is so neglected in modern writings on our art.

Modern medical treatises, although necessarily on subjects having an intensely human interest, are frequently as lacking in vividness and color as the ordinary guidebook; indeed one should be thankful if they are good guide books. This state of affairs is due to the wonderfully minute and patient work expended on collecting facts and describing diseases and drugs. Modern writers on medicine are swamped in these facts, which are often put together without sense of values or perspective. Rabelais' mind was not that of the searcher out of facts.[2] He was a story teller, and he was interested in the human side of his patients, and if a physician studies his writings in this way he will learn many a thing both to his amusement and profit.

Rabelais' situation in life and his opportunities were admirably suited to the work he was to undertake, or perhaps it would be more consistent to say that his work was the result of his genius, and of the situation in which he was placed. He was first a monk, a Franciscan, which was a preaching, begging order, and he must have been a good preacher, as he gained enough by his work to gather a fine library. Besides this, in the monastery at Fontenay-le-Comte, he had the companionship of an older man, and a finished Greek scholar, Pierre Amy. Fortunately also Rabelais had the faculty of intense studious abstraction, which he himself describes as an entire suspension of the natural faculties and exterior senses. Even in this description he could not refrain from a medical addition by saying that a man deep in study had the arteries of his brain stretched tightly like the string of a cross bow. And, by the way, this remark was not an observation, but a pure deduction from the theory that the arteries contained air, and served to convey the anima or spirit to the brain.

During this part of his life, therefore, he had a learned man as a comrade, who brought him in touch with some of the greatest scholars of the age, such as Budeus, and he himself was an assiduous student of the humanities as given in the classic Greek and Latin authors. He was prevented from stagnating and becoming a cloister student by his activities as a preacher, that gave him just the exercise he needed to make full use of what he read. This preaching had necessarily to be addressed to uneducated people, and on the simplest themes, so that he had to speak down to his audience, not up, educating him in that force of moderation and simple description which is so telling in an author.

After thirteen years of this work his fellow monks made it so uncomfortable for him that he had to leave the order.[3] The pretext was his large library. The real reason may have been envy of his success as a preacher. By a dispensation of Pope Clement

*Read before the Chit Chat Club, San Francisco, Cal., January 11, 1915.

VII he was allowed to enter the order of San Benoit, in which, among other privileges, he was permitted to own private property.

He then became the secretary of the friend of his school days, Geoffroy d'Estissac, Bishop of Maillezais, who seems to have loved good living and the society of learned and clever men. The associations here must again have had a decided influence in furthering Rabelais' literary tastes. According to Paul Stapfer it was about this time that medicine and botany became the principal objects of interest to Rabelais, and it was also about this time that he began those restless voyagings that made him one of the most noted travelers of his time.

It was not until 1528, when he was thirty-five years of age, that Rabelais began, in Paris, to really study medicine; it may have even been later, but it scarcely was earlier. He took his bachelor's degree in medicine before the Faculty in Montpellier, November 1, 1530.

Two years after this, in 1532, we find him in Lyons, that was then the literary and commercial center of France, and we find him in the company of the foremost literary men of the time. True to his literary instincts, to his associations, and to his love for medicine, he soon began to write on medical subjects.

When a young man graduates in medicine he often casts about for some subject on which to write so as to attract attention. Often these attempts at scientific work are absolutely worthless, and many of them are wearisome in the extreme, and come to no useful or interesting conclusion. As, however, hope is an accompaniment of youth and even of a fresh start in life, it not infrequently happens that enhusiastic expectations are built upon ordinary or even highly meretricious stuff. The principle on which this custom is based, however, is commendable, and often furnishes an incentive to do scientific work. Quite characteristically Rabelais took up translations, and did the Aphorisms of Hippocrates, the Ars parva of Galen, and the Letters of Manardi into French. These works got him friends, and through them he secured the place of physician to the Grand Hospital of the city of Lyons, a salaried position.

To his renown and to our happiness he soon ceased to write on purely medical themes, and in the same month, November, 1532, that he entered on his service in the hospital he published Pantagruel. As has been mentioned, his natural bent was toward being a story teller, and he was little inclined to the minutiæ and to the patient research that would have fitted him for a scientific career. Nevertheless to the end of his life he always inscribed himself as a physician, and always asserted he only wrote to comfort and cheer his patients.

There is no doubt that Rabelais is gross, and that this together with the old French dialect in which he wrote, constitute decided impediments to his study. There are, however, editions turned into modern French, that in parallel reading render the old French comprehensible, and enable one at the same time to enjoy the style and the diction, and in English we have an admirable translation, Urquhart's.

This translation is so good that a recent edition follows it almost absolutely.[4] It is not without errors, however, one of which, on account of its illustrating Rabelais' fondness for an anatomical joke, may be mentioned here. One of Rabelais' characters, Doctor Janotus, a learned theologian, whom we shall mention later, swears, when stirred to deep anger, Par la ratte Dieu, which Urquhart had rendered, by God's rattle. This is incorrect. This in modern French would be, Par la rate de Dieu, by God's spleen.[5] In the Middle Ages it was customary to swear by God's body, or by His head, or by His wounds, which oaths were undoubtedly all objurgated with due reverence and sincerity of heart, and as among the amenities usual in theological discussion, of which there was much in Rabelais' day. It was, however, reserved to Rabelais to be so minutely particular in his swearing as to swear by the spleen of the deity. In reading Rabelais the impediment due to grossness is another matter. There are many that see nothing else in his works, but I am sure that the more one studies, the more the grossness sinks into the background, and that, finally, the fire of the man's genius is such as to leave almost no impression in the mind but the admirable depictions of human nature.

Without being derogatory to the profession of medicine, I think much of the grossness of Rabelais may be ascribed to his being a physician. As has been remarked he was for several years physician to a public hospital, and a public hospital in those days must have smelt just as strong and no sweeter than roses. Even in my own student days, before the introduction of Listerism, the odor of a hospital ward was nauseating, but it was on a trip to Mexico City and to Guadalajara that I learned to appreciate, both as regards sights and smells, what a hospital in the Middle Ages must have been.

In order to describe vividly obscene and disagreeable incidents it is necessary to be acutely impressionable to them. It does not follow at all that because Rabelais was able to depict grossness strikingly that he was gross. In the authentic portraits we have of him, with his intellectual features and large luminous eyes, he looks anything but gross. Furthermore we know that in his person he was scrupulously clean, and he gives particular directions in regard to the tidiness that a physician should exercise in his dress and toilet.[6] Being so impressionably constituted it follows that he must have been profoundly affected by the sights, sounds, and odors he was compelled to endure in the practice of his vocation and while in the hospital. In addition to this a physician comes in intimate contact with the physiological personalities of people as no other man does, and with the faculty Rabelais had of stating objectively and strikingly what he saw, his observations necessarily had to reflect themselves in his writings.

We must also take into consideration that Rabelais was a monk, and therefore unmarried, and from all we can gather, lived remote from women. In fact in speaking of Gargamelle, the mother of Gargantua, he takes the opportunity to express his contempt for women. After having conducted this estimable woman through a most eventful childbirth, he says that he afterwards learned she died of joy following a feast given in celebration of the return of this very son from the wars.[7] He denies all personal knowledge of this, however, and says that he is interested neither in her nor in any other woman; a truly monastical attitude. Furthermore Rabelais' book is preeminently a man's book, and does not occupy itself at all with the woman's point of view. The essential of these remarks lies in the well-known influence that women unconsciously exert in repressing grossness, especially sexual grossness. Not long ago, when discussing woman suffrage, a well-known

lawyer drew attention to the way language and demeanor had improved in law offices since women had been employed in them. And it is only natural that this should be, for if this check did not exist, society would become a welter of unendurable coarseness.

It would, however, be unfair to say that Rabelais had no esteem for women. His eulogy of a wife at the sickbed is one of the finest in his works, and might be readily passed over as it is put into the mouth of the frivolous, thoughtless Panurge. Panurge quotes the wise as defining a wife as the mother of a family, legitimately married; "Where there is no wife," he says, "there the patient is in great peril." He had observed this clearly in the case of popes, legates, cardinals, bishops, abbés. priors, priests, and monks.

It is so eminently characteristic of Rabelais to enumerate all of the members of the hierarchy to which he himself belonged; and they were the great ones of the earth in his day, greater than kings. They were all celibates like himself. Was this sentence wrung from him in his tender nursing of his dear invalided friend, Cardinal Jean du Bellay? Surely it was a physician, with the heart and soul of a physician, who penned these lines. No matter how many skilled people may be employed, it is always the wife, the mother of a family legitimately married, who stands between the patient and the great peril.

One must also bear in mind that Rabelais was the personification of the spirit of the Middle Ages, and those Ages were coarse with the living, and insanely preoccupied with the materialities of the mouldering flesh of the dead. They had a luxury of disgust in gazing on corruption that we moderns find it hard to appreciate. In modern life the activities and varied interests to a great extent prevent such morbid ruminations finding expression, and Rabelais lived not in modern life but at its dawn, when thoughts and actions were still essentially medieval.

Bearing in mind the age in which Rabelais lived, his occupation, his unmarried state, and his clear vision in depicting what he saw, we think Rabelais was not gross, he was only contemporaneously objective. Furthermore, it must always be borne in mind that art and genius are free, and may occupy themselves as well with the exposition of the horrible and gross, as with the beautiful and good.

Rabelais' works are fragmentary and disorderly, and he himself said they were written at odd moments, and required no more time for their composition than it did for taking his meals.[8] He rambles on, and probably was frequently interrupted in his writing, and this is just the point, for who is more interrupted than a man in the practice of medicine? Rabelais' works are just such as a man with frequently interrupted leisure might write, and they are just such as a man in close proximity, as a physician is, to the weaknesses of human nature might write. Brandes says "Shakespeare was what Rabelais was not, an artist."[9] The conditions under which the two men wrote were, however, very different. Shakespeare had to write a continuous play, and he had to build up well rounded characters to fit into his plays. Rabelais wrote character sketches in detached situations.

Instead of regarding Rabelais as a physician, however, it might be more just to say that he was a writer with a large experience in the medical and physical observation of men, and undoubtedly much of the charm of his work is due to his dexterous management of this experience. For example, a physician more than anyone else knows what a comfort radiant heat brings to elderly people, and in two situations, in the case of Dr. Janotus, and in a scene representing Grangousier seated before a fireplace, Rabelais gives inimitable descriptions of this.

Boys have a natural tendency to play tricks with bells, and it was quite natural that young Prince Gargantua and his companions should steal those of the tower of Nôtre Dame de Paris. Princes in those days were noli me tangere, and therefore instead of sending a policeman or the sheriff to recover the bells, one of the eldest and most imposing members of the Theological Faculty of the Sorbonne, Master Janotus de Bragmardo, was commissioned to negotiate with the young rogues. If Janotus succeeded in his mission, he was to get as a reward for his services six measures of sausages and a good pair of breeches, that he admitted would be a great comfort to his legs. He was getting along in years, and had arrived at a time when men love their ease, and he did so desire to win those breeches! He said that in his youth he was good at arguing, or as they would say in Oxford, a great wrangler, but now he wished to retire to a quiet corner where he could enjoy a good cup of wine, a good bed, and have his back to the fire and his belly to the table with a deep dish, handsomely replenished, in front of him.

The longing of Janotus to get his back to a fine fire is touching. In advanced years the lumbar muscles are so frequently visited by pains, and so grateful for warmth, that immediately the reader is put into sympathy with the character, and wishes him every success in his endeavor. Fortunately his audience, composed of the young Prince Gargantau and his youthful companions, although mischievous scamps, were good hearted and would sympathize with him too. At a later date on the boards of a London theater, Falstaff told Prince Hal rather plaintively, that it did not take much to bring the laugh to the lips when there wasn't a pain in the back. Pantagruel, however, had more easy good nature than Prince Hal. Both Prince Hal and his father Bolingbroke, were hard even to the point of heartlessness, whereas kindly benevolence and universal charity of disposition were dominant characteristics in the Grangousier family.

Returning to the subject of radiant heat as being agreeable to the back, who has not seen an elderly gentleman standing with his back to the fire, with his legs wide apart, with parted coat tails, and gently stroking his hams, his beaming countenance showing how acceptable the heat is to him?

As illustrative of the tender regard in which this part of our anatomy is generally held, I may relate an experience I once had in London. While having some clothes made I remarked to the tailor that the trousers came up very high in the back. They were so high in fact that the suspenders crossed just below my neck. The tailor answered that they were so made in order to protect the kidneys. I perceived what he was driving at. A pain in the back is referred by the laity to the kidneys, and the tailor was catering to the laity both in regard to clothes and to ideas.

And Gargantua himself, out of the generosity of his princely heart, and as a reward for the jolly time Dr. Janotus had given him and his company, also extended presents, among which was cloth for trousers. He went still further in his solicitude and exhibited a due regard for the kind of trousers

that should be fashioned out of this cloth, fearing that they might not be suitable. He weighed this style and that, and paid particular attention to a pattern reaching scarcely to the knees, but having plaits and gathers both above and below that served for the greater solace and comfort of the kidneys. At the same time he also seriously considered a Swiss style, so fashioned as to keep the abdomen comfortable and warm.

But it is not alone the elderly that love to have heat play on the lower part of the body. Have you ever seen a mother washing her baby, and then hold it by its little feet so that the glow of a fire may strike the back of its thighs? The little fellow will squirm and crow and laugh, while the mother hugs it and kisses its little pink toes. It is in such scenes that one appreciates how fine it is that we die when old, and how grateful we should be that nature carries on her work by a continual rebirth.

This lively appreciation of the comfort obtainable from suave and gentle heat is of definite importance in the practice of medicine. In my early life my mental teeth have often been set sympathetically to chattering on seeing a poor devil suffering from typhoid fever put into an ice cold bath. It was no student of the genial humor of Rabelais that invented that form of treatment. One of the best practitioners I know often says he is opposed to anything too hot or too cold, either ingested or applied, and I have no doubt his sense of the ridiculous, of which he is plentifully endowed, has aided him in arriving at this conclusion.

Those who would narrow down a physician's observations to those of disease alone commit a great mistake. A definition of the word physician with them would be a man who listens to people's sorrows and miseries, and endeavors to correct them by the administration of chemicals. A physician's duty is wider than this, as he should not alone study the disagreeable things that a patient may suffer, but must also consider the agreeable things that solace and comfort him in his suffering. Again and again in his prologues, which by the way are masterpieces in prologue composition, Rabelais, as has been before remarked, repeats that his sole object in writing was to cheer and comfort his patients. A good story is told of him in this regard.

In a consultation at which he was present, it was decided to give an aperient. While the other consultants were lengthening out the consultation by conversation so as to appear to be earning their fee, Rabelais slipped out and ordered a fire in the palace court yard, with a cauldron of water suspended over it, into which he caused to be thrown all the keys of the household. When the other consultants finally came out they asked Rabelais what he was doing. He said he was making a key soup, as he understood that keys, with the exception of cannon, were the most opening or aperient things in existence. When the story was told to the patient he laughed so heartily that he recovered.

Of modern writers Anatole France is the one who most nearly resembles Rabelais in bringing the reader into sympathy with his characters by describing their physical disabilities. In Les Dieux ont Soif, for instance, there are at least a dozen references to subjects more or less related to medicine. One of these describes the condition of a vigorous, powerfully built man, who is assiduously engaged in a sedentary occupation, and who eats overmuch. In order to stimulate his overloaded digestive organs, he frequently takes a nip of ardent spirits, which, of course, only affords a fleeting relief to his permanent distress. At the same time the author describes the dull leaden complexion and pitted skin incident to this form of malnutrition that dermatologists call seborrhea, and introduces all these details into his narrative without giving a didactic impression. This is art, and this is the way Rabelais also interwove into his story the impressions he acquired in the practice of medicine. This is, I believe, the subconscious reason why so many medical men read Rabelais. What they acquire in reading him they acquire unconsciously, but it is none the less valuable. In reading medicine one is apt to become crammed and clogged with facts. Under such circumstances writers like Rabelais and Anatole France succeed in giving us clear, fresh, just views, and achieve what Aristotle designated as a mental catharsis or clearing out.

In reviewing Rabelais' life one can see how its course was ordered to bring out his peculiar genius. Even when a schoolboy he became acquainted with the d'Estissacs, who later filled powerful positions both in the Church and in the State, and helped him in many a pinch. After his school days he settled down to life as a monk, that gave him the leisure to study, and the opportunity to apply those studies as a preacher. The immediate practical incentive to work was the desire for money to purchase his beloved books. All this time and later there was the constant association with literary men. Shortly after definitely becoming a physician he resided in Lyons, the commercial and literary center of France, where we find him functionating as the medical superintendent of the city hospital, and writing medical works. Then came that wandering life, more or less connected with the practice of medicine, that must have been such a mental stimulant to a mind so observant and inquisitive. In medicine he saw enough of the hideous, ugly, and transcendently disagreeable, as well as many of the finest traits both in character and in human natural history that served him as material for his wonderful ability as a realistic writer.

Acute Pemphigus Complicating Scarlet Fever.—J. M. Robertson-Ross reports the case of a boy aged ten years in whom on the thirty-second day of an attack of scarlet fever there appeared a bullous eruption which rapidly assumed a fairly general distribution, accompanied by an irregular pyrexia and running a course of little more than six weeks.—*British Journal of Children's Diseases.*

SCOPOLAMINE-NARCOPHINE ANESTHESIA (TWILIGHT SLEEP) IN LABOR.*

By K. E. SCHLOESSINGK, M.D.,
NEW YORK.

THE paper which I shall have the honor to read to you to-night deals with the scopolamine-narcophine anesthesia in childbirth. You will understand and appreciate my point of view when I say that I am not here to talk about "a new era of motherhood," about "the deliverance of womanhood from the curse of labor pains," and other similarly beautiful headlines belonging between the covers of magazines, or to the woman's page of the Sunday newspaper. It is my purpose to describe to you in plain words the technique, the advantages, and the disadvantages of an anesthesia which has been practised for the past eight years in Freiburg and in other European clinics, and which, we may claim, has in many cases eased the bitter hours of childbirth for the women of these days, whose activities and abilities have become more and more mental and less and less physical.

Going back to the first principles which have formed the basis for the development which this anesthesia has had at Freiburg one may briefly define it in this way: The purpose of the anesthesia is to place the patient in a state in which she is but semi-conscious (Dämmerzustand). In this state the patient, to speak in a physiologic-phychological sense, does "perceive pains but does not apperceive pains." The state is similar to that of a person who is suddenly roused from a sleep in the middle of the night and asked a few questions. Though answering those questions at the moment the sleeper will often not remember the occurrence at all the next morning.

The injections of scopolamine have the effect of preventing any sensations leaving impressions in the cortex. And only impressions are capable of being recalled through memory. But it is also undoubtedly true not only that these injections produce amnesia—the original purpose and idea of the Dämmerschlaf—but that in most cases we also obtain a fair analgesia.

We employ "scopolamine stable" and narcophine. Scopolamine stable contains an addition of mannite, a sixvalent alcohol which prevents its disintegration and produces a more even effect in its influence upon the patient. Narcophine is an opiate closely related to morphine except that it contains more narcotine, so that one molecule of meconic acid contains one molecule of both morphine and narcotine. The narcophine disintegrates easily and should not be used after becoming cloudy. The ampoules of scopolamine as put up commercially contain in 1.2 c.c., 0.0003 gm. or 1/200 grain, so that our first dose consists of 1.5 c.c., which is equal to 0.00045 gm. The narcophine we have made up in smaller quantities in a 3 per cent. solution, so that with 1 c.c. we gave 0.03 gm., or ½ grain.

Experience has taught us that hyoscine, considered by many as chemically identical with scopolamine, does not have the same clinical effect. The patients are slower to succumb to the effect of hyoscine and we had a very much larger number of cases of restlessness.

The anesthesia is best produced in a half-dark, quiet room. Sound-proof doors, felt shoes for the nurses, rug-covered floors are unnecessary exaggerations. The patients are very susceptible to sudden light or noise, both waking them easily from their half-slumber. Such a moment of wakefulness may produce an isle of memory (Gauss). And the labor pain felt in this moment of wakefulness may leave in their brains a picture which may enable them to reconstruct the entire act of child-birth, and in this way we may miss our purpose of bringing about a complete amnesia. It is, therefore, advisable to have the patient wear spectacles, in which dark paper takes the place of the lenses, and to have their ears filled with cotton.

The first injection is given when the labor pains reach their full activity, *i.e.* when the uterus contracts regularly every four or five minutes. This is one of the most important points to observe, because too early an injection may bring about a complete cessation of the labor pains. The degree of dilatation of the cervix is less important. Only in cases of dry labor or of occipito-posterior position I wait until I get dilatation of from three to four fingers. It goes without saying that pulse, respiration, and fetal heart should be examined as to their condition before the first injection—an examination which should be repeated before each subsequent injection, though irregularities in the heart action of the fetus which could be traced to the drugs have not been found.

The injections are given intramuscularly and best in the glutei muscles. The first dose consists of 0.00045 scopolamine = 1/140 grain (1½ c.c.) and 0.03 narcophine = ½ grain (1 c.c. of the 3 per cent. solution), which are given separately. The second dose is 0.00015 (1/400 grain) scopolamine and no more narcophine, and is generally given one hour later. The third dose is given after the "memory test" or after convincing oneself of the success of the injections by some other means, half an hour after the second injection. The subsequent injections are given in intervals of from one to one and one-half, or two hours, according to the depth of the "twilight sleep" of the patient. As a rule, as mentioned before, we give the narcophine but once. Only in cases where the patient is restless or does not sleep between the labor pains we give—at long intervals—two or, at the most, three injections of 0.015 gm. or ¼ grain narcophine. About half an hour after the first injection the patient begins to feel drowsy; she falls asleep readily between the labor pains, the face flushes, and the pupils become dilated. Often the skin and the lips begin to feel dry as early as this. This dryness of the skin has induced many to the erroneouse belief that the injection produces a rise of temperature. To give the patient relief she may be given water as often as she demands. The flush, which is purely peripheral, is absolutely harmless.

Half an hour after the second injection the "memory test" should be made. According to Gauss, the entire technique stands or falls with this test, as the dosage is made dependent upon it. Gauss shows the patient some object, a toy, a coin, the watch, or he calls her attention to some action which takes place during labor, such as wiping her face, examination, drinking of water, etc. About twenty-five minutes after he asks the patient whether she remembers the object or the action; if she does not remember, the purpose is attained and one may wait an hour or an hour and a half before giving the next injection. It is, however, very important not to let the patient wake up from her semiconscious state; first, because it is difficult to get her

*Read before the Chicago Medical Society January 26, 1915.

back into it, and, secondly, because one should avoid the "isle of memory." When we expect delivery in three-quarters of an hour, no more scopolamine should be given, as it would have an unfavorable influence on the child.

This "memory test," however, has several disadvantages. First, it assumes a certain amount of intelligence which is very often lacking. Secondly, the showing of a watch or a doll, etc., is such an extraordinary thing during childbirth that it is conspicuous and therefore leaves a stronger impression in the patient's mind. Other tests, on the other hand, leave impressions which are too weak. We know of patients who, when the memory tests were applied, remembered every time the number of injections, and who constantly asked to be given "twilight," but who would place three months back an examination which had just taken place, and who would be entirely anamnestic the following day.

Siegel, of the Woman's Clinic in Freiburg, depends more upon coordination, reflexes, and the general impression he gets of the patient. Anybody who has some experience with this anesthesia will soon know whether the patient requires a new dose, and the impression which he gains of the state of the patient will guide him so that he will not overdose or underdose, both of which should be strictly avoided. A primipara requires, on the average, five or six injections, if seven to nine hours is the average time of the Dämmerschlaf. It is, however, by no means dangerous to give more injections. The maximum dose (poisonous dose) of scopolamine is 0.001 pro dosi and 0.003 pro die, so that one may give without fear from eighteen to twenty injections inside of twenty-four hours. Beiruti reports a case which was over fifty-nine hours in twilight sleep. I myself had one of twenty-six hours, requiring eighteen injections.

Siegel, in his article on twilight sleep in the *Deutsche medizinische Wochenschrift*, No. 21, 1914, reports a somewhat modified method, which he had applied in 220 cases. The underlying thought of this new method is to standardize the number and strength of the injections. To do this Siegel has computed from the great material of the Freiburg Clinic the average dose required to bring about a successful anesthesia. According to his findings he has employed the following method:

1st Injection			0.00045 Scop.	0.03	Narcoph.	
2nd	"	¾ hrs. later	0.00045 "			
3rd	"	1½ " "	0.00015 "	0.015	"	
4th	"	3 " "	0.00015 "			
5th	"	4½ " "	0.00015 "			
6th	"	6 " "	0.00015 "	0.015	"	

One will observe that Siegel in the first place fixes his injections at regular intervals; secondly, that his second dose of scopolamine is equal in strength to the first dose, and, lastly, that with every third injection he repeats the narcophine, but in only half of the strength of the original dose. We personally believe that this method is contrary to the theory of Kroenig and Gauss and that the patients generally do not require such strong doses. I have treated only two cases according to Siegel's new method and have had in both cases, perhaps accidentally, asphyxiated babies.

When during the past summer so many American physicians came to Freiburg it is a very much to be regretted fact that they saw just those cases which were treated with the new technique—a technique which, as Siegel expressly states in his article, was nothing more or less than an experiment. Thus it came about that those who had seen the new technique introduced it in this country and had to abandon it shortly as unsuccessful. Going back to the old technique we obtained the same degree of amnesia with very much smaller doses and with the result of getting fewer oligopneic babies. The great secret of success in every direction is after all to be found by applying careful individualization to each case. To do so will come as a comparatively easy matter to every one with growing experience. For instance, while I used to give formerly on an average of from five to six injections, I now get along with from three to four injections. And as I have found by experience that whenever the mother shows herself very susceptible to the influence of the scopolamine the child is the same, I am very careful with my injections in cases of this kind.

The great advantage of this anesthesia during childbirth is to be found in the fact that it exerts none, or but very little, influence upon the activity of labor. Only the second stage is sometimes somewhat prolonged because the labor pains have not so strong an expulsive power. Siegel computes the prolongation in his primiparæ at one hour and twenty-two minutes for the first stage, and at thirty-three minutes for the second stage. However, there can be no doubt that it is better to leave a woman an hour and a half longer without pains in labor than to leave her the whole time with pains, the more so as this prolongation of labor is in itself inconsequential and only of theoretical value. Besides, we possess to-day in pituitary extract a drug which when properly employed helps us over the possible loss of time. Bandler does not like this anesthesia, saying that it interferes with the use of pituitary extract. Our experience does not confirm this. To the observer who is unfamiliar with this method it may appear as if the interval between the pains becomes greater after the injection. But this is caused by the fact that the woman in most cases will feel only the acme of the pains, and we, therefore, cannot perceive the crescendo and diminuendo of her pains from her expressions. There are women who even in the second stage manifest so little pain that if one does not keep a strict watch one may be surprised suddenly to find the child in the bed.

During the last pains, when the head is coming through, we sometimes give to very sensitive women about 10 c.c. of ethyl chloride to prevent her waking up through the pains which, of course, are strongest at this time. After the child is born the cord is clamped immediately and the child is taken into another room so that the mother does not hear it cry.

During the last stage the oft-mentioned restlessness or excitation which shows in some cases becomes especially noticeable. This is due to the fact that this state is not caused by an irritation of the brain, but by the pains themselves. The woman, who is in a semiconscious state, does not know exactly what is happening to her. She feels pains and does not know just where, and this feeling of discomfort causes her to toss from side to side. And inasmuch as the woman has no coordinated movements, the entire picture creates an even stronger impression. But that the pains themselves are the cause of this state shows most clearly when pituitary extract is given. The restlessness becomes more noticeable just because the pains are getting stronger. In the four hundred and more cases which I have handled in New York, I have seen but

four states of strong excitation in which I was compelled to give ether.

It is a fact that we find more restlessness among women of the lower classes than among women of culture and refinement. The free patients at Freiburg, mostly peasant women from the Black Forest, showed a very much higher percentage of restlessness than the private patients. I have had the same experience in New York—the more intelligent, the more nervous, and the more hyperesthetic a woman is, the better she takes the treatment.

Hemorrhages do not occur any oftener than usual. I have been fortunate enough not to have had one real hemorrhage among my cases here. In Freiburg they measured the loss of blood as carefully as possible, and comparing it with the loss of blood in ordinary cases, did not find any unfavorable results. I had two cases of retained placenta.

Lacerations of the perineum are, according to all reports, of rarer occurrence, as the perineum is stretched more slowly. Siegel reports only six small lacerations in seventy-eight spontaneous primiparæ, or 7.5 per cent., whereas the ordinary percentage is 13.5. Harrar and McPherson report thirty-seven lacerations out of a hundred cases of twilight sleep against forty-five out of a hundred without. Heller and Rongy also report favorable results in this respect.

Operative deliveries can be performed just as usual; small quantities of ether are usually sufficient. Moreover, the number of forceps cases is lessened, for the cases of "convenience" forceps, which make up the greater percentage of forceps deliveries, are eliminated as we know that the woman is not suffering.

After delivery it is best to let the patient sleep. About three hours after delivery she will emerge from her semiconsciousness.

The fresh condition of the patient after childbirth is, according to all authors, remarkable. The woman feels strong and vigorous and demands to get up after a short time. That is because there is no shock after the delivery. It is, of course, an error to assume that the anesthesia causes a quicker involution of the uterus, and if Kroenig lets the women get up twenty-four hours after birth it is for other reasons. By getting up we must not understand that they are tangoing or doing heavy work. They merely retire for a quarter of an hour to the armchair and then return to bed.

We now come to the child. It was the state of the children which created most opposition to the method, and there was justification on both theoretical and practical grounds. As a rule, we are anxious to avoid giving opiates and belladonna to infants, and in this case narcophine and scopolamine are introduced into the child during its uterine life. And that the child is influenced is shown when it is born by the sometimes dilated pupils, the dry lips, and the frequent state of dizziness. We must assume, however, that the selective powers of the placenta prevent the poison from exerting a really detrimental influence upon the child. And, as a matter of fact, the quantities of scopolamine and narcophine which analysis shows in the urine of the newly born are infinitesimal (Holzbach and Gauss).

The state in which the children are often born is, according to Gauss, an oligopnea, not an asphyxiation; it is a sort of dizziness. Clinically, the picture of the children is as follows: The children immediately after being born will take one deep breath, or will even cry; then the respiration will slow down, will become shallow, the heart will sometimes drop as far as thirty, and the child will take on a cyanotic appearance. By leaving the child alone, one will observe that after one to three minutes it takes another deep breath and that the action of the heart improves, and this recurs at constantly shorter intervals until a normal condition prevails. According to Gauss the explanation of this is that the scopolamine exerts an influence upon the vagotonus and the respiratory center, in consequence whereof the child requires a larger quantity of carbonic acid in its blood to stimulate the respiratory center. According to Gauss and Siegel, the best thing is to leave the children alone and do nothing. A very slight effort at resuscitation will, however, bring the child more quickly to a normal condition. We have followed the advice of Gauss and Siegel and have fared well in so doing.

Siegel reports that of 220 children, 148 were born with absolutely normal vitality, 61 were oligopneic, 4 were apneic and 4 asphyxiated; 2 children were born dead and one living child had to be perforated on account of fever of the mother. Of the four asphyxiated children, two were brought back to life, the other two died after living three-quarters of an hour and one hour and a half, respectively. The mortality of the children is therefore exceptionally small, amounting to only 2.15 per cent. Of the 220 children, 213 left the clinic alive and healthy. The total mortality during birth and during the first days of life is therefore only 3 per cent.

The lying-in period is normal. Harrar and McPherson report favorable results in the same directions.

I would like to call your attention especially to the fact that this anesthesia seems to have an exceptionally good influence upon patients suffering from some kind of heart trouble. There can be no doubt that shock and fear during childbirth have considerable influence upon women with cardiac troubles. The elimination of shock and fear under this anesthesia is, therefore, very much in its favor. Besides we know that scopolamine and particularly narcophine have a favorable influence upon the heart. I personally can report over ten cases from my practice in New York. Among these was one double mitral and aortic insufficiency, one stenosis of the mitral valve and insufficiency, two cases of simple stenosis of the mitral valve. The rest were mitral insufficiencies. Except for one case where delivery was spontaneous, all the women were delivered with forceps after complete dilatation. In all these cases, where the patients easily reacted under the drug, I got along well with three injections and less, and I had complete success in all cases.

Zweifel of Doederlein's Clinic reported some time ago several cases of eclampsia which showed up favorably under the treatment. We have had a number of cases of threatening eclampsia too, and we incline to give the anesthesia credit for the successful course of delivery.

I do not want to forget that this method is perfectly applicable in any well-kept and properly equipped private residence.* But permit me to point out again the necessity that the physician should take time to observe the patient continually or to leave with her a nurse trained in obstetrics.

*In my cases in private houses I never had any difficulties or bad cases.

Needless to say that the members of the family, who are under all conditions a nuisance, should be kept at a proper distance.

I have had only four cases of still-born babies among the approximately 450 cases in the different hospitals. The autopsies proved in one case congenital transposition of the viscera, in another edema of both temporal lobes, the third was undoubtedly a strangulation by the cord, and the fourth was born dead and macerated. Nine children died within the first ten days.

Heller reports 272 cases, in which the treatment was given in most of the cases by myself: Primiparæ, 210; multiparæ, 62. Total average dose for primiparæ, 0.0012 (1/50 grain); for multiparæ, 0.001 (1/66 grain). Total average duration of the anesthesia for primiparæ, 7 hours; for multiparæ, 3½ hours. Amnesia, 212 = 78 per cent.; partial amnesia, 32 = 12 per cent. Failures, 28, three cases could not be brought under, the others were admitted too late. Spontaneous birth in primiparæ, 71; in multiparæ, 53. Low forceps, 44; perineal tears, 45; breech extractions, 3; twins, 2 pairs. Still-births, 3 (transposition of viscera, macerated child, strangulation by the cord). Spontaneous crying, 224; oligopneic, 44; asphyxiated, 3; 7 died in the first 10 days (1 melena, 1 spina bifida, 1 subdural hemorrhage, 1 edema of the glottis, 1 bronchopneumonia, 1 premature child, 1 in which the cause was doubtful).

Abnormal positions are not contraindications, though it is advisable in such positions which in themselves show a high mortality of children (breech presentations) not to apply this method, so that the failure may not be attributed to the scopolamine. For the same reason it should be avoided in cases of premature children. With the above restrictions, the method is also applicable when inducing labor.

Conclusions: Scopolamine-narcophine anesthesia has—when applied in the right way—no dangers for mother or child. We demand a continued observation of the patient not because we expect some undesirable accidents, but because in case of possible complications we want to be certain that the method should not get the blame.

The anesthesia can be applied not only in the hospital, but in any well-appointed residence, demanding, however, constant observation on the part of a skilled obstetrician who must be thoroughly familiar with the technique in order to avoid over or underdosage.

The method scarcely prolongs the labor; on the other hand, it helps the woman through her ordeal by actually lessening the pains considerably and blotting them completely from her memory.

Operative confinements are more rare, so are lacerations of the perineum.

Disadvantages are the sometimes occurring restlessness and the sometimes occurring but harmless oligopnea of the children.

Summing it up we may say that we are, thanks to Kroenig and Gauss, at last in possession of a non-dangerous anesthesia which frees women from the dreaded labor pains. The knowledge of such freedom saves her from months of anxiety and fear during pregnancy and she faces her hour of trial less nervously.

And we may hope that at least one factor among the causes of race suicide, viz., the dread of pain when giving birth, will have lost much of its force.

86 Madison Avenue.

AN IMPORTANT GROUP OF SKIN DISEASES.

By CHARLES F. PABST, M.D.,

BROOKLYN, NEW YORK.

ASSOCIATE DERMATOLOGIST, BROOKLYN HOSPITAL AND DISPENSARY.

Instead of selecting one disease for my topic I have chosen a group which may be considered a unit when discussing affections of the skin. In this manner several distinct diseases can be studied comprehensively in the same space of time that it would take to read a long, stereotyped article on a single malady, which anyone could refer to in one of the standard text books. Although this fact is especially true regarding diseases of the skin, it would also prove useful and advantageous if applied to the entire field of medicine. Points of similarity would be perceived quickly, and slight differences between the various lesions would be understood readily, so that differential diagnosis would no longer remain a difficult task.

We are all too prone to scan the horizon for something "new" while Opportunity is standing by our side waiting to be noticed. Many articles that are bristling with "newness" fall far short of perfection because all that is new in them is not true, and all that is true is not new. Numerous theories are interesting to listen to or read about, but they endure but a short time—like the snowflake on the river, a moment there, then gone forever.

In presenting the vegetable parasitic diseases grouped under tinea trichophytina, or ringworm, I do not offer a subject which is new, but one which is full of interest and which can be studied easily, if properly classified. Ringworm may attack the scalp, the beard, the nails, or the general body surface, so that the most serviceable classification is that based upon the part of the body affected. The following varieties are found:

1. Tinea Circinata, ringworm of the smooth body surface.
2. Tinea Tonsurans, ringworm of the scalp.
3. Tinea Sycosis, ringworm of the beard.
4. Tinea Cruris, ringworm of the genito-crural region.
5. Tinea Unguium, ringworm of the nails.

I have added to the above list for the purposes of convenience, three diseases which are not due to the ringworm:

A. Tinea versicolor, or chromophytosis, which is due to a vegetable parasite called the *Microsporon furfur*.

B. Tinea favosa, which is due to a vegetable parasite called the *Achorion schoenleinii*.

C. Sycosis, which is not due to a vegetable parasite, and is therefore entirely different from tinea sycosis, or barber's itch.

Before describing the various forms of ringworm it is advisable to consider briefly the fungus which causes this disease. The fungus is tinea trichophytina, or ringworm, which may be divided into two main groups:

1. *Trichophyton microsporon* or the *Microsporon audouini*.

2. *Trichophyton megalosporon*. (*a*) Endothrix, which occupies the center of the hair shaft and usually invades the hairs of the scalp (tinea tonsurans). (*b*) Ectothrix, which occupies the intrafollicular region, forming a sheath between the hair and the follicles, and usually attacks the hairs of the beard (tinea sycosis).

The fungus is best studied by placing some of

the epidermic scales on a microscopic slide, adding two drops of a 10 per cent. potassium hydroxid solution, applying a cover glass and examining with an oil-immersion lens.

We will consider first tinea circinata, more properly known as tinea trichophytina corporis, or ringworm of the body. It is caused by the *Trichophyton microsporon* or *megalosporon*, and is conveyed from the horse, dog, or cat, and frequently by way of combs, brushes, and towels. The face, neck, and hands are the usual sites of the lesion, which begins as a small scaly patch, usually pink in color and having a slightly elevated border. These patches tend to spread peripherally and heal in the center, thereby producing the characteristic annular or ring shape. The patches are usually few in number, rarely numerous. In the tropics this affection is more severe and obstinate, and is called tinea imbricata, the entire body often being covered with patches and heavy scales.

The treatment of tinea circinata is chiefly local. Tonics consisting of arsenic, iron, or quinine, may be administered if required. This disease is either entirely cured or not cured at all. The clothing must be boiled and brushes, combs, and towels should be disinfected. Locally, the skin should be thoroughly cleansed with soap and water. Avoid medicated soaps. Various parasiticides may be applied, but I have found a 10 per cent. solution of oleate of mercury in olive oil the most beneficial. Twenty drops of oil of cade, and half a dram of alcohol may be added if desired. Whatever agent is used to destroy the fungi must be used persistently, and the patient should be kept under close observation for some time after the disease is apparently cured in order that treatment may be resumed promptly in case of recurrence.

Tinea tonsurans, or tinea trichophytina capitis, also known as ringworm of the scalp, is caused by the *Trichophyton microsporon* or *megalosporon*, usually by the *megalosporon endothrix*. The onset is the same as that described under tinea circinata. Signs of the disease soon appear in the hairs, however, which lose their luster, become brittle and present a broken-off appearance. They become grayish white in color, due to the presence of the fungus. There is a moderate amount of itching associated with this condition, but no pain, and the treatment is the same as that given for tinea circinata.

Tinea sycosis, also known as tinea trichophytina barbæ, barber's itch, parasitic sycosis and ringworm of the beard, is caused by the *Trichophyton megalosporon ectothrix*. The word "sycosis" is derived from the Greek, meaning a fig, and is used because the moist, red surface of the lesion resembles the pulp of a fig.

Tinea cruris is in reality a variety of tinea circinata, and is sometimes called eczema marginatum. The patches are brownish red instead of pink, and an eczematous condition is often present in addition to the ringworm. The fungus present is either the *Trichophyton microsporon* or *T. megalosporon*.

Tinea trichophytina unguium, or onychomycosis, or ringworm of the nails, is a rare condition affecting two or three nails which become thickened, brittle, and opaque. It is a chronic disease and difficult to cure.

Tinea versicolor, known also as pityriasis versicolor or chromophytosis, is caused by the *Microsporon furfur*. Small yellowish macules first appear on the chest, shoulders, or abdomen, rarely on the extremities. These areas increase in number and coalesce, producing irregularly shaped yellow patches. In treating this condition the clothing and all articles capable of harboring the parasite should be carefully disinfected. The body should be scrubbed daily with a mild soap and hot water. A solution containing one dram of sodium hyposulphite to the ounce, should be applied twice daily. I have obtained good results with a solution of mercuric chlorid, one grain to the ounce.

Tinea favosa, or favus, is caused by a vegetable parasite the *Achorion schoenleinii*. The lesion usually appears on the scalp, and begins as a superficial inflammation, followed by the formation of small yellow crusts about the hair follicles. There may be suppuration, which is the cause of the permanent baldness which sometimes follows this disease. The diagnosis is made by the sulphur-yellow color of the crusts, the scarring, and the presence of the *Achorion schoenleinii*. Ringworm is of shorter duration, the patches are round, the intense redness is absent and the hairs have a broken-off appearance. The diseased hairs should be removed, and the same treatment applied as recommended for tinea tonsurans.

Sycosis, also called sycosis vulgaris or sycosis non-parasitica, is an inflammation of the hair follicles caused by pyogenic organisms. Each lesion is always perforated by a hair. This disease should not be mistaken for tinea sycosis or barber's itch, and the following points of differentiation should be noted:

Tinea Sycosis.	Sycosis Non-Parasitica.
1. Spreads rapidly.	1. Spreads slowly.
2. Exceedingly contagious.	2. Slightly contagious.
3. Presence of small red areas, which heal in the center and spread peripherally.	3. Presence of pustules, perforated by a hair.
4. Deep structures involved.	4. Superficial structures involved.
5. Slight suppuration.	5. Free suppuration.
6. Slight pain and moderate itching.	6. Intense pain, itching and burning.
7. Hairs diseased; dull and brittle.	7. Hairs normal.
8. Hairs removed easily and without pain.	8. Removal of hairs causes pain unless suppuration is marked.
9. Sometimes causes permanent alopecia.	9. Permanent alopecia is very rare.
10. Mustache rarely affected.	10. Mustache frequently affected.
11. Fungus present (Tinea Trichophyton Megalosporon Ectothrix).	11. No fungus present.

In treating sycosis vulgaris, iron and arsenic should be administered internally because this affection is due to pyogenic organisms which necessarily produce constitutional disturbances. Autogenous staphylococcus vaccine is often used with excellent results, but there are many cases which derive no benefit at all from the vaccine treatment. After softening the crusts with olive oil, the hair should be removed by shaving. This should be repeated every other day at least and continued indefinitely. If shaving causes excessive pain, the

hair may be removed by applying the following mixture:

℞

Barii sulphidi		2½ dr.
Zinci oxidi		
Amyli	āā	gr. 75.

M. et Sig:—Mix to a paste with water, and apply for five or ten minutes. Depilation should be resorted to if pus is present in abundance. Severe inflammation should be treated with soothing applications, such as ten grains of the mild mercurous chloride to an ounce of cold cream. When the marked inflammation has subsided, disinfectants may be applied. A solution of bichloride of mercury, two grains to eight ounces of water is very efficient, or an ointment may be used containing twenty grains of ammoniated mercury to the ounce of cold cream. The *x*-rays have been employed with success in some cases, but they do not always effect a cure. In some instances electricity causes a permanent loss of hair, but even this defect is well endured if the treatment eradicates the disease.

In presenting the foregoing group of skin diseases, I have endeavored to demonstrate the essential points wherein these lesions differ, and trust that the classification offered may prove of assistance in correctly diagnosing these affections.

396 Franklin Ave.

TWO CASES OF LARYNGEAL OBSTRUCTION, AND ONE OTHER.

By CHARLES GRAEF, M.D.,

NEW YORK.

THE following cases are reported for their interest and value. While it is probable that these will be less to others than to those immediately concerned with the operations, such experiences seem sufficiently worth while to justify publication.

The first case was brought to Lincoln Hospital in the ambulance in November, 1914, the "bus" having been called because the patient was suffering from severe dyspnea. I saw the case about an hour after admission and was given a brief history by the interne.

CASE I.—S. F., æt. 36; suffering for several months with hoarseness and difficult breathing. Had become notably worse in past three days. No specific history. Trouble had been thought to be tuberculosis of the throat. The patient was propped on pillows and breathed with effort in stertorous inhalations. All the extraordinary muscles of respiration were in play. He was able to speak in a whisper, with gasps for breath.

I had him taken to an adjoining room for examination and found with the laryngoscope a massive tumor closing the larynx so that nothing of the cords proper could be seen, only a narrow fissure permitting air to pass with difficulty. To get a better view I passed a curved probe over the epiglottis to hook it forward. The patient had shown no especial increase in his distress up to this point but almost immediately after, while the epiglottis was being lightly pressed toward the base of the tongue, he began to show signs of impending suffocation. I released the tongue at once and removed the instruments from his throat to let him recover from the spasm. He did not recover, however. The difficulty increased instead. He made a number of furious choking but futile efforts to breathe, his face turned livid and in a moment or two he rolled over on the couch glassy-eyed, and to all appearances dead. As no preparation had been made for operation of any kind I had only one interne with me at the time. Of course we were not idle, but knowing that artificial respiration would prove of slight if any value we could do little until it became certain that there was no chance of his recovery unless the trachea was opened. I hurried to the instrument room which was some distance away and came back as quickly as possible with a tracheotomy tube and the first scalpel I could reach. There was no time for choice. As quickly as possible I did an emergency tracheotomy; no easy task under the circumstances. He was a short, thick-necked individual and I cut into a large engorged vein in the effort to penetrate the cricothyroid space. The very free bleeding added to the difficulty, but I finally succeeded in placing the tube in the air passage. We were compelled to continue artificial respiration for a very considerable time before the patient began breathing. This he finally did and was returned to bed in good condition. The tumor of the larynx was diagnosed as a gumma.

It is worthy of note that any laryngeal growth carries with it the danger of a sudden and fatal closure of the air passage from comparatively slight cause. A spasm of choking or coughing may provoke an edema which proves the last straw and the swollen mass shuts off the already narrowed passage completely. Two cases of this kind with death were reported recently from the Manhattan Eye and Ear Hospital.

CASE II.—H. R., æt. 11; referred to me by Dr. J. P. Ogden; had been suffering for several days with an acute otitis and mastoiditis for which an operation was required. She had pain, with much tenderness and boggy edema over the mastoid on the left side. Her throat was clear, with moderate sized tonsils.

While in the anesthetic room being put under ether she began to bleed from the nose—not very much but enough to be annoying to the anesthetist. He explained when the patient was brought into the operating room that he thought he had bumped the nose a little with the inhaler but she was nicely under and ready for the incision. The operation proceeded as usual, the bone being found very widely diseased, with much pus, granulations, and necrotic tissue throughout. It required an extensive operation, and I became so much interested in clearing out the disease that I did not pay much attention to the anesthetist. Toward the end of the operation he appeared to be in difficulty, however, and reported that the child was acting badly. Increasing trouble then rapidly followed; and breathing soon ceased entirely. Fortunately this time plenty of assistants were at hand. The head of the table was immediately lowered, the mouth opened, the tongue and the lower jaw drawn forward. Artificial respiration was steadily kept up. Stimulants by hypodermic were given and finger stretching of the rectum was also applied in the effort to restore the child. As considerable bloody, frothy mucus was in evidence about the mouth I had the throat swabbed, and luckily, among the blood-stained mucus, caught hold of a mass of membrane-like material which I succeeded in drawing from the throat. It looked much like the membranous moulds of the larynx and trachea which are sometimes coughed up by diphtheria patients, and I thought at first it must be something of that type. It was over six inches long and almost half an inch thick. It proved, however, to be a firmly-organized blood clot. After the removal, efforts to resuscitate the child were continued until finally breathing was established and she was returned to her bed in good condition. I was compelled to plug the nose to stop the bleeding. Next day I examined the nose and found a spouting vessel in the center of a small ulcer on the nasal septum. This was cauterized and the bleeding stopped.

I learned from the parents that the child had a number of nose bleeds during the days preceding the operation, but as she was suffering much with the inflamed ear and had a good deal of fever, the nasal bleeding was not considered of much moment. The hemorrhages, while lasting for an hour or more at a time, were not profuse and were overshadowed by the ear symptoms.

Undoubtedly the clot had been lying in the nasal fossæ for some time before the child was operated upon. The recurrent bleeding in the fevered patient had slowly built it up and permitted the firm, fibrous-like organization. Under the influence of the anesthetic with the more vigorous efforts of breathing, the ether itself, and the manipulation of

the head, the clot had become loosened and in part drawn into the larynx.

If I had not luckily got this cleared out the case would have, in all likelihood, gone on record as a death due to ether anesthesia. I had looked at the child's throat, but not in the nose, when examining to determine the need for operation. No evidence of any blood clot was observed, and even if I had been told about the nose bleed I would not have thought it necessary to examine post-nasally for a clot.

Such experiences as these are of course very trying and are worth recording, I think, as illustrating some of the many possible ways in which unexpected trouble may arise in surgical work.

Instances of sudden edema or closure of the obstructed larynx occur fairly often in cases of tumor developing in this part. We are told that the taking of iodide of potassium has a tendency to provoke this danger. In the face of such experiences as the one here given it seems likely that medication may have little to do with it, the fact being that a very slight local irritation may start a coughing or choking attack which will do the trick. If the touch of an instrument on the epiglottis can do this, it is reasonable to believe that inspissated mucus, or food particles, lodging on a sensitive part of the throat, or even a swallow of fluid "passing the wrong way" while drinking, may provoke the congestion, edema, spasm, or all combined, which proves to be the fatal "last straw."

I have operated in a great many cases of mastoiditis and have had my share of odd experiences with them, as every operator must have in time, but the one detailed above was unique with me and may be of worth to others.

A third case of somewhat different type which was under my care recently may be of interest also.

Case III.—Mrs. J. G., æt. 32; the wife of a minister in Trenton, N. J., was brought to me for dyspnea due to a very unusual cause. Troubled with faulty nasal breathing for several years, she had submitted to an operation on the turbinates of the right side some months before I saw her. The operation was done under local anesthesia and for some unexplained reason was very long-drawn out—over two hours, she said—the operation being excision of part of the middle and of the inferior turbinates. There was a great deal of hemorrhage, and the patient became much exhausted by her long siege in the operating chair.

From time to time she coughed out the blood which passed from the nose into the throat. Some of the coughing efforts were severe and of course accompanied by strong inspiratory movements. Although small pieces of tissue were secured by the operator the larger bony fragments escaped and were drawn into the larynx—eventually finding their way into the bronchi of the right side. From this time on she had a great deal of severe spasmodic coughing; pain, with harsh breathing and râles developed in the lower lobe of the right lung. She had a finely developed chest but any attempt to take a full breath showed limited expansion on the right side and caused sharp pain.

I have before me a letter written to me by her husband on February 11, 1914, from which I quote: "I am very glad to say that Mrs. G. has entirely recovered from the effects of her operation. The operation was performed on Dec. 7, 1912. Mrs. G. coughed up the first bone some seven weeks after the operation. After this her coughing was not so frequent, yet at times very violent. We had thought that all the bone was up, but we were mistaken, and in May, 1913, after our visit to you, and almost six months after the operation, she coughed up another bone somewhat smaller in size than the first one. From that time her cough abruptly ceased and she has not coughed since. The first bone was more than one-half inch long and three-eighths of an inch wide, and the second was a little smaller." She was brought to me for bronchoscopic examination in the interval between the expulsion of the two fragments. The symptoms detailed above were all in evidence at that time and she likewise had clinching proof in the bone fragment which was undoubtedly a piece of turbinate. It was clean and dry when shown to me. I decided to have an *x*-ray examination made as a possibly helpful agent in locating the foreign body in the lung and as circumstances prevented this being done for a few days I strapped the chest firmly with adhesive plaster over the affected side. It occurred to me that this would not only be a comfort to her but might aid her in the coughing efforts to expel the trouble-maker, and fortunately this worked out nicely for she coughed up the second bone within a few days.

Such an accident in any nasal operation must be very rare, and occurring in a case of turbinectomy under local anesthesia is certainly extraordinary. That this patient recovered without more serious results is no less so.

1125 Boston Road.

TWO CASES OF MONOCULAR OPTIC NEURITIS.*

By HOWARD F. HANSELL, M.D.,

PHILADELPHIA, PA.

The two patients whose affections are described below came for treatment about the same time to the Hospital of the Jefferson Medical College. Both presented indubitable signs of optic neuritis of moderate grade, limited to one eye. They were young women, aged seventeen and fifteen, respectively; apparently healthy, complaining of nothing but partial loss of vision in one eye. In the one case the vision was reduced to the perception of light, and in the other all objects had lost their individual colors and had become yellow. Both had been engaged in their daily occupation and neither could give any cause for the failure of the sight.

The problem that interested all the men working in the dispensary was the determination of the underlying cause. Orbital affections were unanimously ruled out because of the absence of paralysis of the muscles, of exophthalmus, of edema of the lids or conjunctiva, and of limitation of movement. It was agreed that a constitutional disorder was responsible, most probably nephritis or a brain tumor. Both from the character of the occupation pursued by the patients, one a sewing machine operator and the other a factory hand, and from the freedom from all indicating symptoms the diagnosis of an acute infection seemed to be excluded. In neither case could the assumption of disease of the brain or the membranes be accepted, because, aside from the optic neuritis, no sign pointed to that conclusion. And yet a brain affection in its incipiency cannot be positively excluded. Continued observation only can determine its presence. The same reflections apply to the assumption of nephritis.

Case I.—Girl, aged seventeen, white, single, sewing machine operator, was admitted to the hospital December 16, 1914. She stated that on November 23 severe pains on the left side of the face and head began, lasting two days. Shortly afterward she became conscious that the sight of the left eye was blurred and since then it has been growing worse until now it is reduced to the perception of light. There has been, since the first two days, no headache, nor has she suffered from nausea or vomiting. Her father died at the age of forty-seven from nephritis. Her mother, a brother and a sister are living and in good health. Three other children died in infancy, one of membranous laryngitis, and the others from unknown causes. The patient has had the ordinary diseases of childhood and is a fairly robust, healthy looking girl.

*Read before the Section on Ophthalmology, College of Physicians, Philadelphia, January 21, 1915.

Vision of right equals 20/20 and the eye is normal in every respect. The pupils are equal, the right reacting normally to light and convergence; the left reacts but sluggishly and to less extent. Consensual reaction is marked from right to left, but only faintly present from left to right. The extraocular muscles are in balance. Tension is normal.

In the left eye the media are clear. The disc margins are obliterated and the adjoining retina edematous and elevated. The veins are full and tortuous and the arteries diminished in caliber. There are no hemorrhages or other changes in the fovea or in the retinal periphery.

Physical examination disclosed no organic lesion. Repeated examinations of the urine were negative; Wassermann test negative; von Pirquet test negative; complete blood count negative. The sinuses accessory to the orbit are clear; "atrophic" rhinitis and pharyngitis sicca is the report from the Laryngological Department. Roentgen-ray plates showed the sella turcica to be normal in size and the clinoid processes prominent but smooth.

The visual field of the left eye is slightly contracted concentrically with enlargement of the blind spot. No scotoma; occasional and transient blindness for red and blue.

From December 16 to December 23 she has received inunctions of mercury, iodide of potassium, and a daily sweat bath. On the last date vision equaled 20/100. The swelling of the nerve head and the retinal edema are less, the veins also more nearly approach their normal caliber and course. The improvement continued until the day of the last ophthalmoscopic examination, January 13, when vision equaled 20/50. The disc had become pale and its margins were hazy, the physiological cup was filled in and the veins were only slightly tortuous.

Case II.—White girl, aged fifteen, a factory hand, was admitted to the Jefferson Hospital December 10, 1914. She stated that for ten days all objects perceived by the right eye appeared yellow and she had difficulty in seeing small objects and reading. She had no ocular pain, headache, vertigo, or other symptoms. The family and personal history are irrelevant.

Right vision equals 20/100; left 20/50, improved to 20/20 by — 1.50 ax. 90°. The media are clear. The disc margin of right is entirely obscured by a glistening white snowbank deposit, which extends well into the retina. The disc itself is swollen from edema. In the macular region is a perfectly formed, star-shaped figure of whitish spicules radiating from the fovea. There are no hemorrhages and the fundus otherwise shows no lesions. The veins are quite distended, but are not tortuous.

The left eye is free from disease of any description. The pupils are equal and react normally to light and convergence, the left more slowly and less extensively than the right. The consensual reaction is diminished from right to left and normal from left to right. The muscles are in balance; the rotations and tension normal.

Physical examination showed no bodily lesion. Twelve analyses of the urine revealed no sugar, albumin or casts, and the urea was of average percentage; Wassermann test negative; radiograph negative. The nasal septum was deflected to the left and pressed upon the middle turbinate bone. The sinuses were clear and the blood count normal.

The right field is slightly concentrically contracted and the blind spot is enlarged. The color fields are not limited.

December 22.—Right vision equals 20/70. The disc is less edematous and the star-shaped figure in the macula is disappearing, only the tips of the spicules remaining.

January 8, 1915.—Right vision equals 20/50. Macular region is almost entirely clear and objects no longer appear yellow. The nerve head is still edematous. The treatment was identical with that given to the first patient, namely: sweats, mercurial inunctions, and potassium iodide.

Groenouw and Uhthoff say that the ophthalmoscopic picture of albuminuria retinitis is typical when white plaques are present in the fundus and the star-shaped figure in the macula. The same findings exactly are, however, found in brain tumor. Schmidt and Wegner (*Arch. f. Ophth.*, XV., 3, 253) observed them, together with choked disc in a patient with glioma of the brain, but sound kidneys. De Schweinitz and Thomson (*Arch. of Ophth.*, 24, 2) make the same observation in a patient with occipital tumor. Moreover, these changes are not always present in nephritis. Mauthner believes that a poorly marked macular figure in the absence of other retinal changes speaks against the diagnosis of nephritis.

As a rule, retinitis of nephritis involves both eyes, although months or even a year or more may pass during which time one eye remains entirely free from the ophthalmoscopic changes characteristic of the disease. Weeks mentions a case in which the right eye was blinded by retinitis albuminuria followed by glaucoma, and the left eye remained sound for fifteen months. Schlesinger (Inaug. Dissert., Berlin, 1884) observed a patient where one eye remained free for two and a half years. The retention of the health of one eye is not attributed to the greater resisting power of that eye or to any predilection of the disease for one eye more than for the other, but has been ascribed by Cheatham (*J. A. M. A.*, 1885) to the presence of one diseased kidney only and that on the side of the diseased eye, or by Yoest (*Rec. f. Ophthal.*, 1883, p. 145) to the presence of only one kidney in the patient.

That the so-called typical picture of the retinal changes in nephritis may be present as an indication of disturbances of circulation and alteration in the tissues of the retina called forth by a primary disease of the arteries and veins—endarteritis and endophlebitis and their consequences—and due to other and entirely different diseases has been repeatedly demonstrated. For example, congenital lues, Lawson and Sutherland (*Oph. Rev.*, 1899, p. 89). Scarlet fever (*Phila. Med. Surg. Ref.*, 1873). Measles, Sotvio (Jahr. f. Kinderh., Bd. 50, p. 1). Erysipelas, Vossius (*Klin. Monatsb. für Augenh.*, XVIII, 410). Lead poisoning, Despres (*Gaz. des. Hop.*, 1872, p. 1180), and Lehman (Inaug. Dissert. Halle, 1890); also Galezowski (*Rec. d'Ophthal.*, 1878, p. 104). Ankylostoma infection, Nieden (*Centralb. f. prak.*, August, 1903). Carcinoma Ventriculi, Pick (*Klin. Monatsb. f. Augenh.*, XXXIX, 177). Brain tumor, Williams (*British Med. and Surg. J.*, May, 1901). Chlorosis, Mackenzie (*British Med. Journal*, I, p. 328), and Riegel (*Münch. med. Wochens*, p. 1138, 1899). Diabetes, Anderson (*Ophth. Rev.*, 1889, p. 33); Desmarres, Traité des Maladies des Yeux, 11 Ed., Vol. III, 521); Noyes (Trans. Am. Ophthal. Soc., 1869-71); Urne (*Arch. Med. Belges*, Nov., 1875); Tany (*Berl. klin. Wochens.*, Nov., 1878). Scorbutus, Mackenzie (*Lancet*, II., 25, 1880). Malaria, Koslonski (Ref. Jahrb. f. Ophth., 1878); Richard (*Gaz. des. Hop.*, 1863).

The resumption of normal appearances in the macular region is possible also in nephritis. In especially favorable cases the previously observed changes disappear without leaving a trace and the vision may reach its former acuity.

In the first case—moderate optic neuritis without retinal changes—the improvement in vision and diminution in the swelling under treatment by mercury and iodides suggests a luetic cause. It seems to me we should go farther in our investigations and not accept a diagnosis based on therapy. It is well known that these remedies, especially when their administration is combined with that most effective adjunct, excessive diaphoresis, tend to absorb any exudation irrespective of its cause. Moreover, the patient exhibited none of the vascular or retinal changes associated with syphilitic optic neuritis.

Wilbrand and Saenger (Bd. 5, p. 7) say "Nearly all inflammations of the optic nerve may be favorably influenced by therapeutic measures. Since in the majority of cases the etiological moment is an infection or intoxication so the course and prognosis depend largely on the influence of treatment upon the primary condition. Certain forms, for example acute axial neuritis, which for the most part are monocular, must in the absence of assignable cause, be attributed to repeated exposure to cold and they offer a favorable prognosis for the vision but not for the general condition. They are often precursors of multiple sclerosis or myelitis." The affection originates in and is confined to the optic nerve; it is generally monocular and confined to young individuals, particularly females between twelve and twenty-four years of age.

NON-BACTERIAL URETHRITIS.

By P. I. NIXON, M.D.,

San Antonio, Texas.

Ordinarily in the conception and experience of most of us a purulent urethritis is synonymous with gonorrhoeal urethritis; and in the great majority of instances such a conclusion will be justified by the bacterial findings. However, one is surprised to find in the exceptional case not the gonococcus but some of the other pyogenic organisms, notably the staphylococcus and streptococcus; and very exceptionally one will find the causative organism to be the *Micrococcus catarrhalis*, a diplococcus that is very closely akin in its morphology and staining qualities to the gonococcus. It is true, then, that the gonococcus overshadows all other causes of urethritis in frequency, persistence, and importance, but it is well always to establish microscopically that this bacterium is or is not present in each individual case.

What has been said in reference to non-specific pyogenic urethritis is applicable to traumatic urethritis from instrumentation and irritative urethritis following the ingestion of certain drugs by the mouth; these too are the exceptional finding. It is fairly well established also that venereal contact may be followed by a urethral discharge, in the pus of which the gonococcus and oftentimes other bacteria cannot be demonstrated. The classical case of Neisser is cited, in which he "failed to find any bacteria in the pus from the urethra of a man who, a few days after returning to his wife from a long absence, developed purulent urethritis, and brought suit for divorce, offering his disease as evidence."

Briefly in this paper I want to call attention to a small group of cases illustrative of another type of purulent urethritis, namely, that following prophylactic or curative injections into the urethra. I have chosen to call this type non-bacterial urethritis, but chemical or irritative urethritis would perhaps be more appropriate, as cultures were not made from the discharge of these cases.

A urethral discharge following the injection of a chemical antiseptic is inseparably bound up with the question of aborting a urethral infection. All of us have occasionally had the happy fortune to cut short an early urethral discharge by using strong solutions of the various silver salts. Prophylaxis of venereal infection has long been advocated and is now extensively practised in the army and navy of the United States; this consists in the injection of a 2 or 3 per cent. solution of protargol in glycerine or a 10 to 20 per cent. aqueous solution of argyrol and the use locally of a 30 to 50 per cent. calomel ointment, the latter, of course, being directed against the possible development of syphilis. These measures, rigidly enforced, have reduced markedly the incidence of venereal disease in both branches of the service; it is the consensus of opinion among medical officers that if this treatment is administered within 8 hours of exposure, protection is almost certain and that it should be practised even up to 48 hours after exposure. It is obvious how many prophylactic treatments would follow as a natural result of the curbed sexual propensities of soldiers and sailors. In one report of about 6,000 treatments, there followed only 105 cases of venereal disease, but there is no mention of cases of urethritis resulting from the injected solution.

So it will be seen that a non-bacterial or irritative urethritis of the type mentioned above is exceptional. It appears plausible that such a result would ensue only in those who have an abnormally irritable or non-resistant urethral mucosa or possibly an idiosyncrasy to the drug used. In passing it is worth while mentioning that all my cases occurred in blonds. It has been said that the physician who gives the treatment for gonorrhea to all cases with urethral discharge is doing no wrong to the patient's anatomy at least. Such an opinion, however, is not confirmed by the cases comprising this report, as in every instance cessation of discharge was simultaneous with the cessation of all treatment.

The diagnosis, then, is of no little importance in that the treatment is totally different from that to be advised in true gonorrhea; on the one hand the treatment is aggressive and persistent, general and local; on the other it is entirely negative. The importance of diagnosis is to be emphasized, also, in those cases where the moral status of an individual might be affected by proving the specificity or non-specificity of a urethral discharge.

Briefly there follow abstracts of four cases. The first two were the results of therapeutic injections, whereas the last two followed prophylactic measures.

Case I.—J. F., age 28; an unmarried man; developed a purulent discharge on April 1, 1914. He was seen three days later when large numbers of gonococci were present in the discharge. An unsuccessful attempt to abort the infection was made, daily injections of 3 per cent. protargol being given at the office together with injections by the patient of ½ of 1 per cent. protargol and hexamethylenamine in large doses by mouth. The posterior urethra became involved and the chronicity of the case was most troublesome. On May 28, 2 months after the onset, the patient was discharged apparently cured, although he still had a few shreds in the first glass of urine. Contrary to my knowledge, he continued to use the protargol injection. Six weeks later he returned with a profuse discharge which to the naked eye had all the earmarks of gonorrhea. He related that the discharge reappeared soon after his dismissal and had been constantly present ever since. A prolonged search failed to reveal either gonococci or other bacteria in the pus. The patient was advised to leave off the treatment. The following day the discharge was much lessened and by the second day it had disappeared and the patient has remained well.

Case II.—R. J., age 21; unmarried; was seen April 4, 1914, with a discharge of four days' duration. In the discharge were found gonococci. The abortive treatment used in Case I was employed here for about a week. Then permangate of potassium irrigations were instituted and given fairly regularly till April 23, fourteen days after the beginning of the treatment. On this date and on several previous visits, no gonococci could be found. After this date the patient suddenly

quit coming. A week later he showed up again and gave as explanation of his absence the fact that he had been in jail. After reviewing his experiences and indulging at some length in remarks not altogether complimentary to the hygienic condition of our city jail, he consoled himself by saying, "One good thing: I got rid of my gonorrhea over there and I didn't have my medicine with me." The discharge had ceased a day or so after his arrest, and when I saw him there was no sign of it and his urine was perfectly clear. He was seen two months later and had had no further trouble.

Case III.—R. W.; a married man of thirty; was seen August 1, 1914. The circumstances preceding the development of his discharge were as follows: his family along with that of one of his friends (a man of 35), was spending the summer in the mountains. Each week end these two men would visit with their families. The latter part of August they had as a visitor a young widow who returned to the city with them. The following Monday the friend of my patient spent the night with the widow in question; on Tuesday night my patient had a similar experience, although ignorant of the happenings of the previous night. The first man developed a urethral discharge on Wednesday of the same week and obtained from his physician an injection of 10 per cent. argyrol. My patient hoping to take time by the forelock, when he learned of his friend's condition began the use of the same injection on Thursday. On Friday he developed a discharge and was seen Saturday in a state of great alarm and uneasiness. A profuse purulent discharge was to be seen exuding from the urethral meatus; one was surprised, however, to find no bacteria in stained smears. The injection was discontinued and the discharge ceased two days later and has not recurred.

Case IV.—Mr. A., age 38; single, was seen October 13, 1914. One week before he had intercourse with a woman about whom he knew nothing. Three days later he consulted a physician who prescribed a 20 per cent. argyrol solution as a prophylactic injection. A urethral discharge developed 5 days after exposure and 2 days after beginning the use of the injection. On examination the meatus was found to be red and swollen, and a purulent discharge was present. Repeated examinations of the pus failed to reveal the presence of gonococci or other bacteria. The discharge ceased immediately after the injection was withheld.

205 Hicks Building.

THE CAUSES OF PERSISTENCY AND INCURABILITY OF CERTAIN AFFECTIONS OF THE GENITOURINARY TRACT.

By A. STRACHSTEIN, M.D.,

NEW YORK.

ATTENDING GENITO-URINARY SURGEON, HAR MARIAH HOSPITAL, ATTENDING ADJUNT GENITO-URINARY SURGEON AND CHIEF OF CLINIC, BRONX HOSPITAL.

The urologist is frequently called upon to answer the question whether infections of the genitourinary tract are at all curable. This is particularly aimed at gonorrhea and its complications.

The interrogator is not only the patient, but frequently also a colleague, the general practitioner. And why does this cry of despair come from both? It is justified from their point of view, because here is a given case apparently of a trivial nature and yet persists for many months and even years in spite of treatment. I know of one prominent colleague who expressed himself that so far as therapeutic results are concerned, "I would rather have syphilis than gonorrhea." Yet, in spite of this despondency, the urologist is in a position to state most emphatically that these so-called incurable cases remain uncured for the want of a correct and proper diagnosis as to the cause of the persistency. I venture to say that each one of these incurable cases has some hidden focus which has been overlooked and naturally failed to bring forth the rational treatment for that particular case.

The intelligent use of the urethroscope combined with the true microscopic interpretation of the expressed secretions from the various glands that empty their products into the genitourinary tract, are such powerful guides in the hands of the urologist that at no time need the hidden enemy remain undetected and beyond the range of successful attack.

I shall quote some cases of my own practice and some from Prof. Wossidlo's clinic (Berlin) that will illustrate many of these points.

Case I.—J. B., 34 years; salesman; contracted specific urethritis two years ago. Was variously treated for over one year, but could not rid himself of his inconstant morning drop and particularly from shreds in his urine. For some months he dropped treatment as useless. Contemplating marriage, he consulted me on October 28, 1914, about his condition. Following were the findings: First urine clear with many curled up shreds; second urine clear with a number of wedge shaped pieces and debris. Prostate normal in size and consistency; seminal vesicles not palpable. Microscopic examination of the expressed prostatic secretion shows a few leucocytes, no genococci. Urethroscopic examination of the posterior urethra with the Wossidlo irrigation urethroscope revealed floating plugs of pus attached to the openings of the prostatic glandular openings on the floor of the prostatic urethra. Anterior urethra showed the presence of a soft infiltration, and nearly all the lacunae of Morgagni were enlarged and chocked with plugs of matter.

Treatment.—The patient was started on methodical gradual dilation of the entire urethra once a week, using the Oberländer-Kolliman irrigation dilator. Twice a week the prostate was massaged and soon followed by deep irrigation of silver-nitrate 1-4000 by the Dididay method. This *modus operandi* was carried out for seven weeks with the following results: His morning drop disappeared, the second urine portion became clear, but the first urine still contained small curled shreds. Anterior urethroscopic examination showed the lacunae still covered with plugs of matter. These were then cauterized through the urethroscope once every four days in three sittings until the anterior urethra assumed a normal aspect, and he became free from shreds. Prostatic secretion showed only an occasional leucocyte.

Case II.—L. K., age 35; tailor; married; denies any previous venereal disease. He assured me that since marriage, he had no relations with any other woman but his wife. Six months ago he developed slight burning upon urination, his external meatus somewhat pasted together, but no free urethral discharge. He consulted his family physician who diagnosed the malady as gonorrhea. No smear was made. After treating him for four months with the silver salts, practically no progress was made and he developed an occasional morning drop and complained of the shreds in both urines. His physician gave him up in despair and advised him to consult a specialist. Thereupon, the patient went to a busy hospital clinic where he was treated for nearly two months making but little headway. On November 2, 1914, he consulted me and upon my suggestion he brought his wife for examination, but smears from her urethra and cervix were negative. She had had no previous treatment. His own examination showed first urine clear with long heavy filaments; second urine portion clear with considerable debris. Prostate small, upper part of right lobe is soft, boggy, and tender. Seminal vesicles not palpable. Prostatic expressed secretion revealed numerous leucocytes some micrococci, and some short thick rod-shaped bacilli, no genococci. The anterior urethra showed a moderate soft infiltration; microscopic findings were similar to those of the prostate.

Treatment.—Patient was at once started on prostatic massage twice a week, having filled his bladder previous to each massage with a solution of oxycyanide of mercury 1-5000 and instructed him to empty his bladder immediately after the massage. Once a week he was also gradually dilated with the Oberländer-Kollman irrigation dilator, using same solution for the entire urethra. Internally he used one of the formaldehyde group of urinary antiseptics. After continuing in this mode of treatment for eight weeks, his urine became free from filaments or debris, and the prostatic

expressed secretion showed only two to three leucocytes to each field of vision.

Case III.—(From Prof. Wossidlo's Clinic.) Man of 36, conductor, had gonorrhea seven years ago from which he recovered without any complications. From fear of reinfection he abstained from sexual intercourse but was in the habit of practising masturbation to a moderate extent. Six to eight weeks ago he developed painful and frequent urination occasionally accompanied by terminal hematuria. No urethral discharge. Was treated by his family physician for some time for cystitis, but without improvement. Upon examination his urine was clear, but contained many shreds. Posterior urethroscopy revealed an enlarged and engorged colliculus covered by many minute polypaid vegetations. This was painted with silver nitrate 20 per cent. in three successive sittings and while there was a marked reaction each time, his urine finally cleared up and he was relieved from his symptoms.

Conclusions.—1. The persistency of symptoms for a long time, in spite of treatment, is usually due to failure of localization of the focus of disease.

2. Case I was rebellious to treatment because of his mild prostatic involvement as well as the lacunitis which was overlooked.

3. Case II was undoubtedly a bacterial nonspecific urethritis from the outset. The use of the silver salts added a chemical irritation of the mucosa and favored the growth of the invading germ.

4. Symptoms arising from the involvement of the colliculus are frequently mistaken for those of cystitis, but can be diagnosed with fair ease by resorting to posterior urethroscopy.

17 East Thirty-eighth Street.

AN ELECTRICAL MOUTH LIGHT.

By ALFRED KAHN, M.D.,

NEW YORK.

The instrument herewith illustrated represents an electrical mouth light, which I have found of marked utility in my practice, as an ear, nose, and throat specialist. Its advantages are many. I offer this reason for presenting it to you. Its essential features follow:

The cuts make the mechanism and appearance of the instrument clear. The illustration shows the light as being made up of an electrical flashlight mounted on a system of hinges (universal joints), the hinges connecting the light with a fiber mouthpiece, which is grooved to receive the teeth. The instrument, which is extremely light, may thus be

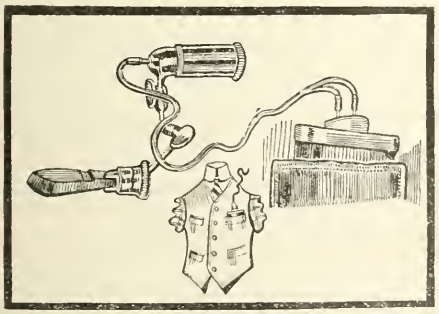

Fig. 1.

held firmly in the mouth. The universal joints enable the light to be manipulated quickly in any direction where it remains firmly in position. The hands are left entirely free for any operative or other procedure. The light receives its power by means of a dry battery (which can conveniently be placed in the coat or vest pocket); or if desired the instrument can be connected to the regular street current, reducing the voltage by means of a rheostat.

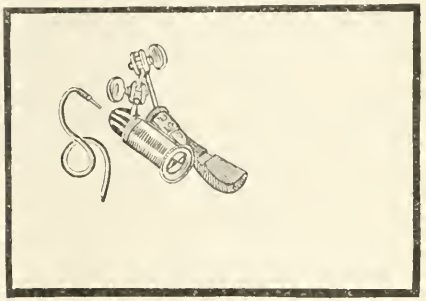

Fig. 2.

The light is strong and regular. The instrument can be used for any purpose for which our present headlight is used (eye, ear, nose, throat, rectal diseases, vaginal examinations, etc.).

Figure 1 shows the light connected to a dry battery; placed in the vest pocket. Figure 2 shows its compactness; in what small compass it can be folded and tucked away. The battery will burn this light about four hours continuously, long enough for most operations.

The battery and light are regular stock articles and can be secured at any electrical store. This light is of special utility at the bedside or where an operative procedure is to be done in a private home. The instrument can be easily sterilized. Its cost is most reasonable.

34 East Fortieth Street.

Medicolegal Notes.

Who Are Itinerant Physicians.—In proceedings in the Texas courts, where it was charged that the defendant had engaged in and pursued the occupation of a physician, traveling from place to place, without having paid the tax levied on that occupation, it was held, on appeal, that the evidence did not sustain a conviction. It showed that the defendant had been a resident of Vernon, in the county of Wilbarger, for more than a year at the date of the institution of these proceedings, and would show him guilty of violating that provision of the Texas Code prohibiting any one from practicing medicine without having obtained a license from the medical board and registering it, and not the article preventing one from practicing medicine as an itinerant physician without having paid an occupation tax. Had he paid the occupation tax, under the evidence he would not have been authorized to practice medicine, and, as the evidence clearly showed that his fixed residence since he had come to the state had been at Vernon, he would not be liable for the tax levied on traveling physicians.—Rutherford v. State, Texas Criminal Appeals, 169 S. W. 1157.

Instituting Baseless Actions for Injuries.—A physician conspired with certain attorneys to obstruct justice by inducing a person to believe that he had been injured, and to institute suit for injuries alleged to have been sustained in a collision with a vehicle driven by the defendant's servant, when in fact no injury whatever resulted from the collision. In an action for contempt of court the Kentucky Court of Appeals holds that the physician's acts being wholly accomplished before any suit was instituted he was not guilty of a contempt of court nor punishable summarily therefor, but he was guilty of obstructing justice, a common-law misdemeanor, and was punishable therefor by ordinary proceedings.—Melton vs. Commonwealth, Kentucky Court of Apeals 170, S. W. 37.

MEDICAL RECORD.

New York, April 10, 1915.

AN ATTACK ON THE HEALTH LAW OF NEW YORK STATE.

LAST week we commented briefly upon the first annual report of the New York State Public Health Council, congratulating our fellow citizens upon the results of the council's activities and upon the framing of a new sanitary code for the State. And even as we were penning the lines several bills were being introduced into the State Legislature which, if adopted, would seriously cripple the work of the commissioner of health and nullify the new sanitary code.

These bills, fathered by Assemblyman Hinman of Albany, five in number, are in the shape of amendments to the public health law. The first (Int. 1561) is directed against the commissioner of health and instead of the present injunction that he "shall not engage in any occupation which would conflict with the performance of his official duties," orders that he "shall devote his entire time to the duties of his office." This is perhaps the least objectionable of the proposed amendments, apart from the insulting innuendo concealed in it, for the duties of the commissioner of health are so exacting as practically to demand his entire time in any case. The second bill (Int. 1600) will, if it becomes a law, seriously interfere with the sanitary work in the State, for it reduces the number of sanitary districts from a minimum of twenty to a maximum of ten, and at the same time fixes the salary of the sanitary supervisor of each district at a maximum of $2,500. In other words, it doubles the labors of the sanitary supervisor and reduces his salary about 20 per cent. The third amendment (Int. 1601) makes permissive, instead of mandatory, the establishment of divisions in the State Department of Health and gives the commissioner the power to increase or decrease the number of these divisions, to consolidate them, or to change the name of any division at his pleasure. This is an altogether unnecessary interference with the existing law, and if it had any effect it would be in the line of decreased efficiency as making the divisions impermanent and liable to change at the whim of any one in power for the time being. The fourth amendment (Int. 1602) strips the Public Health Council of its power to define the qualifications of directors of divisions, sanitary supervisors, local health officers, and public health nurses hereafter appointed. The introducer's object in this amendment is not apparent, but the result of its enactment would inevitably be to open these appointments to unqualified persons and to create a number of jobs to be given in reward for political services. The fifth and worst of this series of bad bills (Int. 1603) would deprive the Public Health Council of the power to establish sanitary regulations, would delegate this to the Legislature, and would even abolish the present sanitary code unless it shall be approved by the present Legislature—and how much chance it would have of being approved by a legislature which had already adopted these amendments one can well imagine.

These, briefly stated, are the bills by the enactment of which it is proposed to impair the efficiency of the Health Department and to vitiate the work it has already accomplished. What may be the reason for the introduction of these bills it is difficult to understand. Their passage would not be in the interests of economy, for the worst of them, if passed, would not save the State a dollar, and others would rather increase the expenses of health administration by reducing the efficiency of the department, by putting the formulation of a new code in the hands of inexperts and of men ignorant of sanitary science, and by opening many of the most responsible positions to incompetents. No business can save money in that way. The entire appropriation asked for by the Health Department is only about $400,000—a paltry sum in comparison with the saving of lives and of dollars as well, which it is certain will result if the present law is let alone.

As a direct result of the work of the Department during the past year there are two thousand persons, one thousand of them children, alive to-day in this State, outside of New York City, who would have been in their graves but for the efforts of Dr. Biggs and the Health Council. Are Mr. Hinman and his colleagues in the Legislature willing to let these and three or four thousand others (for the life saving in public health work is cumulative) die next year in order to save thirty-five thousand dollars in the salaries of the sanitary supervisors who are to be dropped?

We can not believe the Legislature will pass these reactionary amendments or, if it does, that the Governor will sign them. But it will be better to spare both the Legislature and the Governor trouble by killing the bills in committee. This would doubtless be their fate if every physician would at once file his protest with the chairmen of the committees which now have the bills under consideration. In such protest the bills should be referred to by their introductory numbers and the protest should be addressed to the chairman of the respective committee as follows: Introduction Number 1561 (the first one above mentioned), Judiciary Committee, Assemblyman Frank B. Thorn, Chairman; Int. 1600, Ways and Means Committee, Assemblyman Alexander Macdonald, Chairman; Int. 1601, 1602, and 1603, Public Health Committee, Assemblyman Gilbert T. Seelye, Chairman. We need not add that prompt action is needed to save the State from this threatened calamity.

NEWER CONCEPTIONS OF MENINGITIS.

THE recent occurrence of this disease in England in epidemic form has stimulated the investigation of many important problems in connection with the distribution of the disease, its prophylaxis, and the recognition of the early stages of meningococcus infection. A number of papers dealing with these aspects appear in the *British Medical Journal*, March 13 and 20, 1915. A. Lundie, D. J. Thomas, and S. Fleming, medical officers attached to the Aldershot command of the British Army, have evolved a novel conception of this disease in its clinical phases. According to this conception cerebrospinal meningitis is more prevalent than is generally known. There are three stages: the catarrhal, the septicemic, and the meningeal. The first of these is regarded as very prevalent, and is characterized by the presence of a pharyngitis alone or in conjunction with a laryngitis. There are no constitutional symptoms and the only objective sign may be a simple redness of the pharynx. Careful bacteriological examination of the secretion of the latter shows the presence of meningococci. These are regarded as responsible for the pharyngitis for the following reasons: The meningococcus resembles the gonococcus in having great vitality in a favorable nidus. The organism has a tendency to enter wandering cells and eventually to travel into the blood stream where it may cause no symptoms other than a toxic headache usually attributed to influenza. Instead of the disease progressing to this stage, it may remain local, and then it spreads over a greater area, including the larynx. Instead of the living cells entering the blood stream there arises a condition of perimucosal induration which causes considerable tenderness and difficulty in swallowing. The symptoms are aggravated by the association of other organisms such as the *streptococcus maximus*. The meningococcus like the gonococcus has a tendency to enter the leucocytes which protect it from the action of the antibodies. Considerable importance is attached to the early recognition of the catarrhal stage of meningitis, for only by this means can one gauge the extent of an epidemic. Practically all meningococcus carriers suffer from nasopharyngeal catarrh, so that in dealing with the large aggregations of individuals in an army, it is a simple matter to pick out as suspects all those who give evidence of this catarrh and to isolate them for bacteriological examination.

The septicemie stage of meningitis is generally not diagnosed. The palate is red and spotted and covered with minute vesicles. The pharynx is inflamed. The voice is often husky and there may be a dry harsh cough. There may also be a profuse nasal discharge. Herpes labialis is common. The temperature is elevated, the face is flushed, and the conjunctivæ are injected. There is some degree of mental confusion, and the reflexes are greatly exaggerated. During this stage the meningococci are probably present in the blood. They have been isolated from the urine and from the cerebrospinal fluid.

The third or meningeal stage comes on after varying intervals and is the stage which presents the clinical picture generally recognized as meningitis. The fact is emphasized that at this stage the disease is already far advanced and in a large percentage of cases fatal. The diagnosis of the condition during the catarrhal stage enables one to carry out an efficient treatment by spraying the throat and the administration of autogenous vaccines.

J. A. Arkwright in discussing the epidemiology of meningitis in the light of bacteriological knowledge, points out that the large number and the widespread distribution of carriers and the small number of cases of meningitis compared to the population force upon one the conclusion that the total number of persons who harbor the meningococcus should be looked upon as constituting the true epidemic. This is a conception of vast importance in preventive medicine.

TREATMENT OF LOCALIZED TUBERCULOUS LESIONS.

THE treatment of surgical tuberculosis by heliotherapy was first put upon a sound basis by Dr. A. Rollier in 1903. His three hospitals are situated in the Vaudois Alps, Switzerland, and have an altitude which varies from 3,800 to 4,500 feet. Owing to the fact that mountain air is pure and dry the luminous and caloric radiation of the sun suffers but slight loss. It is for this reason that the best results from heliotherapy are obtained at high altitudes. Although the brilliant work of Rollier and his associates have stimulated interest in his method in many parts of this country it is naturally to be expected that the mountainous and plateau region of Colorado with an altitude which seldom falls below a mile above sea level would be the place from which we should get the most promising results.

In an advance report concerning heliotherapy and ionic medication as employed at Las Animas, Colorado, C. J. Holeman, passed assistant surgeon, U. S. Navy, speaks very favorably of heliotherapy as applied to cases of tuberculous bones, joints, and sinuses (U. S. Naval Bulletin, January, 1915). The method of application consists in first exposing the feet and ankles to the sun for a period of five minutes during the hours of sunshine of the first day, then the legs and knees for periods of ten minutes on the second day, gradually increasing both the area and the time of exposure until the patient is uncovered to the solar activity during the entire day. The pigmentation is the important element, inasmuch as it produces in the skin a remarkable resistance, favors cicatrization of wounds, and confers a local immunity to microbic infection. In Rollier's paper presented to the XVII International Medical Congress at London in 1913, all his cases for eleven years were tabulated and out of the 1,129 patients 951 were reported as cured. Holeman's advance report mentions the details of five cases (one knee joint, two hip joint, one Pott's disease, and one empyema), all of which showed remarkable improvement in both the local conditions and the general health under the application of heliotherapy.

Perhaps of even more interest than the successful

application of heliotherapy to cases of surgical tuberculosis is the new method described for the treatment of laryngeal lesions incident to the disease. This consists in an application of the principles underlying the ionization of metals. Iodine ions are directed to the diseased larynx in the following manner: A few minutes after the internal administration of 20 grains of potassium iodide a felt pad soaked in a 2 per cent. solution of zinc sulphate is placed in immediate continuity with the positive metal electrode. A large wet negative pole is then placed in an indifferent position near the back of the neck and a current of from 75 to 150 milliampères is applied for from 10 to 20 minutes. The ionizing current passing through the throat at the time that the drug is being eliminated by the mucous membranes directs the iodine directly to the diseased tissues. That this actually occurs is proven by the fact that the patient will experience the taste of iodine while the current is passing. The details of seven cases with marked involvement of the upper air passages are described, and Holeman concludes his report with the statement that "every case treated has been relieved and all have been made quite comfortable."

A NEW TYPE OF INDUSTRIAL POISONING.

THE greatly increased activity in aeroplane and seaplane factories occasioned by the European war has brought to light a new type of poisoning. This has been observed in an outbreak of toxic jaundice among the workers in the Hendon Aeroplane Factory in England and reported by W. H. Willcox in the *Lancet* March 13, 1915. The poisoning is attributed to the use of "dope," or cellulose varnish, which consists of a solution of acetate of cellulose in a mixture of benzine, acetone, methyl alcohol, and tetrachlorethane. Several coats of this varnish are applied to the calico stretched on the framework of the aeroplane wings, forming a firm, airtight, and waterproof coating. The symptoms of poisoning have been found to be due to the tetrachlorethane, which is a powerful liver poison, causing a jaundice of the toxemic type. The symptoms are of insidious onset and consist of general malaise, drowsiness, anorexia, nausea, retching in the morning, unpleasant taste in the throat, constipation usually, and headache. Abdominal discomfort is present in some cases. After a few days or a few weeks jaundice develops in association with the characteristic stools and urine. The vomiting now becomes more marked. There may arise mental confusion, stupor or delirium, and finally coma. Purpura and hematemesis may be present, and in the severe cases death results. If the patient is removed from the influence of the poison in the early stage of the disease the symptoms clear up, although it may take several weeks before the jaundice disappears.

There are a number of interesting clinical features characterizing the action of tetrachlorethane upon the liver in aeroplane workers. The onset is insidious. The acute stage is of comparatively long duration as distinguishable from that of acute yellow atrophy of the liver. The disease is to be differentiated from Weil's disease or infectious jaundice by the absence of pyrexia. There is no anemia such as occurs in the case of hemolytic poisons like arseniureted hydrogen. The jaundice is deeper than that usually seen in delayed chloroform poisoning. Aeroplane workers differ in their susceptibility to the influence of tetrachlorethane, which is a powerful narcotic poison expending its effects chiefly upon the liver and kidneys.

TYPHUS FEVER SIMULATED BY CEREBRO-SPINAL MENINGITIS.

THAT when some pestilence threatens a locality false diagnoses are bound to be made among ordinary disease material is a fact well known, although the bearing is not always the same. Expectant attention may cause a physician to believe that the epidemic is already at hand; while on the contrary, the sharpened knowledge and zeal of a practitioner may cause him to recognize a sporadic case, even if the latter did not arrive from without. Well authenticated cases of clinical cholera have been described in communities in which quarantine had stayed an approaching epidemic. Without the menace of an epidemic, these cases would have been overlooked as cholera and the condition would have been given another name—some form of ptomaine poisoning, very probably.

It is, of course, obvious that in recent years a bacteriological diagnosis or a serum diagnosis suffices to clear up many doubtful cases, notably the various enterogenous infections. In the following instance, however, no such aid could be employed. It was reported by Umber at one of the military medical evenings in Berlin (*Berliner medizinische Wochenschrift*, February 8). A recruit who had not yet been ordered to the Eastern frontier was seized with colic, diarrhea, vomiting, and a feeling of severe malaise with fever of 38° C. (102.4° F.). This picture was followed by severe chills and general myalgia, which caused a provisional diagnosis of pneumonia. The symptoms now invaded the upper air and food passages. A general catarrhal process attacked the conjunctivæ, nasal fossæ, throat, mouth, and bronchi. The tongue and throat became swollen. The sputum contained streptococci. The patient, his mind clear, was on the borderline of collapse. On the next morning his temperature was 40° C. (104° F.), and the mind was confused. An eruption had appeared on the upper abdomen and back, which at first suggested a typhoid roseola, but the spots very quickly became petechial and extended over most of the surface. Typical roseola was, however, always present, and the spleen had become enlarged. The mental state had become one of apathy. Widal test and blood cultures were negative. The diagnosis was therefore true typhus, concurred in by experts. The patient, isolated, died in a little over twenty-four hours from the first chill. Autopsy showed cerebrospinal meningitis due to the *Diplococcus intracellularis*. It is to be remembered that cerebrospinal meningitis has always been recognized largely through its petechial eruption.

Iodized Carbon in the Treatment of Infected Wounds.

An apparently effective method of employing iodine as a surgical dressing has been devised by L. Lemaire (*Presse Médicale*, February 18, 1915). This method consists in the use of a true solid solution of iodine in animal charcoal. In 1857 Warington discovered that if animal charcoal is mixed with iodine, the latter enters into a peculiar physical combination with the former. The phenomenon is one of absorption, in which there is a condensation of the iodine on the surface of the carbon molecules with the result that both substances acquire new physical and chemical properties. Lemaire used an iodized carbon containing ten per cent. by weight of iodine. This was dusted upon infected wounds in the same manner as surgical powders are ordinarily used. The results are said to have been excellent. The antiseptic action of the iodine in its altered state was supplemented by the absorptive property of the carbon, a property that has long been recognized. One advantage over tincture of iodine is the fact that iodized carbon releases its iodine quite slowly and is therefore devoid of any caustic action.

News of the Week.

Belgian Relief.—Dr. J. Riddle Goff of the Committee of American Physicians for the Aid of the Belgian Profession, writes: "In ye ancient times there was a cry from Macedonia 'Come and help us.' St. Paul took that as the voice of God and responded with spiritual and mental pabulum. To-day there is a cry from Belgium, 'Send us food or we perish.' This is just as much the voice of God as the cry that reached St. Paul—and the response is even more necessitous. The pictures of wretchedness in that pitiful land grow more and more appalling from day to day. Miss Winifred Holt, secretary of the New York Association for the Blind, has just returned from Europe where she went in the interest of the blind Belgian refugees. She says there are no exact data, but it is estimated that one person in every 1,200 in Belgium was either partially or totally blind, or a total of about 8,000. When Belgium became the hotbed of war there were thirteen institutions for the blind, and deaf and dumb. These were all wrecked and their sorry inhabitants poured forth in a mad rush of surging masses of blind men and women and children, seeking such guidance as they could get, groping for places of safety. They must now be scattered among the helpless, starving, unfortunate refugees standing in the breadline that stretches all over Belgium. The president of the National Relief Commission of Brussels asserted on March 25 that before the next harvest 2,500,000 Belgians will be in the breadline. Foodstuffs must be continued to be provided in the fairly regular way in which they have been supplied heretofore. Belgium has been saved from the intermittent periods of starvation by the personal sacrifices of the directors of the American Commission, who have at these times pledged their personal credit for as much as $10,000,000. All honor to them. We of the medical profession of America must see to it that our Belgian colleagues and their families are saved from such intermittent periods of starvation by keeping the stream of food and supplies pouring into them in a steady flow."

The treasurer, Dr. F. F. Simpson, 7048 Jenkins Arcade Building, Pittsburgh, reports the following contributions for the week ending April 3, 1915:

Dr. John Lewis Stevens, Mansfield, Ohio	$5.00
Hoquiam Surgical Club, Hoquiam, Wash	10.00
Dr. J. D. Griffith, Kansas City, Mo	5.00
Dr. Philip F. Williams, Philadelphia, Pa	5.00
Visiting Nurse Association of Chicago, Chicago, Ill.	12.00
Dr. Burnley Lankford, Norfolk, Va	5.00
Dr. Irene M. Morse, Clinton, Mass	3.00
The Homochitto Valley Medical Society, Natchez, Miss.	14.25
Dr. T. L. Macdonald, Washington, D. C.	10.00
The Yankton District Medical Society, Yankton, S. Dakota	50.00
Dr. James D. Voorhees, New York, N. Y.	25.00
Receipts for week ending April 3rd	$144.25
Previously reported receipts	5,752.25
Total receipts	$5,896.50
Previously reported disbursements:	
1,625 Standard boxes of food at $2.20	$3,575.00
945 Standard boxes of food at $2.30	2,173.50
Disbursements for the week ending April 3:	
64 Standard boxes of food at $2.30	147.20
Total disbursements	$5,895.70
Balance	$0.80

To Control Typhus in Serbia.—A party of American physicians sailed from New York last Saturday on the *Duca d'Aosta* for Naples, where they will porceed to Serbia to stamp out the typhus epidemic from which that country is suffering. In the party were Dr. Thomas Wright Jackson, chief sanitary inspector; Dr. Hans Zinsser, professor of bacteriology at Columbia; Dr. B. W. Caldwell of the Canal Zone; Drs. A. W. Sellards, George C. Shattuck, and F. B. Grinnell of Harvard, and W. S. Standifer and Luis de la Peña. The last two were members of General Gorgas's staff in the sanitary campaign that rid the Isthmus of Panama of yellow fever. With Dr. Richard P. Strong of Harvard, who is already in Europe, these men compose the membership of the American Red Cross Sanitary Commission, organized to clean up Serbia. The expenses of the commission will be borne jointly by the Red Cross and the Rockefeller Foundation. The commission will work in harmony with others sent by England and France, under the general direction of an executive committee composed of Dr. Strong, Sir Ralph Paget, and Dr. Joubert of Paris. Of the American Red Cross units sent to Serbia, four physicians and twelve nurses have had the fever and one physician, Dr. Donnelly, has died of it. Of the Serbian army and volunteer surgeons nearly two hundred have died of typhus.

American Surgeons Thanked by the French Government.—At the opening of the eye department of the military hospital in Paris on April 2 Dr. Louis Borsch of Philadelphia, in charge of the department, was formally thanked by Surgeon-General Fevrier for the services of himself and other American surgeons in caring for French wounded. The surgeon-general said that the work of the Americans was highly esteemed by both the Government and the people of France.

Smallpox in Vienna.—During the week ending March 13, 73 cases of smallpox were reported in Vienna, and from the first of August to the middle of March there were 1,041 cases of the disease with 229 deaths.

A Potent Pediculicide.—At a meeting of the Vienna Medical Society on March 14 Prof. Sigmund Fraenkel announced that he had accidentally discovered in anisol a substance which would absolutely kill the body louse which is the carrier of the typhus germ. He was experimenting with oil of anise, which seemed to have some effect, and wrote

to his laboratory "diener" to send him another bottle. The servant misread the order and sent anisol instead of oil of anise (anisöl), and Professor Fraenkel was astonished to find that he had stumbled upon a certain destroyer of the insect.

The Limit in Movies.—A license has been refused a movie theater in New York to run films illustrating the advantages of twilight sleep in childbirth. We do not know how much of the process is illustrated in the show, but, much or little, it hardly seems to be a fit subject for public exhibition. The moving pictures were to have been explained in a lecture by a disciple of Kroenig and Gauss, who has lately come to this country from Freiburg.

Automobile Accidents.—Twenty-one persons were killed by automobiles in the streets of this city during March, 1915, as compared with twelve during the same month last year. In the State outside the city nine were killed, as against two a year ago.

Testimonial Banquet to Dr. Jacobi.—A testimonial banquet will be tendered Dr. A. Jacobi by his friends and admirers under the auspices of the Bronx Hospital and Dispensary on the occasion of the eighty-fifth anniversary of his birthday, on May 6, at the Hotel Astor. The medical men on the Committee of Arrangements are: William J. Robinson, chairman; Arpad G. Gerster, Willy Meyer, S. W. Lambert, J. Brettauer, Francis Huber, A. A. Berg, M. Rehling, H. Edwin Lewis, M. Arouson, Otto Schirmer, Max Rosenthal, Henry Heiman, A. L. Goodman, A. Hymanson, Alex. Goldman, A. A. Brill, A. L. Goldwater, H. Schumer, H. J. Epstein. The price per cover will be $3. Reservations for seats should be sent to Dr. A. L. Goldwater, treasurer, 141 West 121st street.

The Missouri Valley Medical Society, which met in Omaha the last week in March, will hold its autumn meeting in Des Moines on September 16 and 17. At the meeting just closed Dr. F. H. Albee of this city delivered the roation in surgery, taking as his subject "The Future of the Bone Graft."

Dr. Frank H. Holt, assistant superintendent of the Boston City Hospital, has resigned to become superintendent of the Michael Reese Hospital, Chicago.

Increased Pay for Medical Examiners.—A bill is before the Minnesota Legislature raising the pay of members of the State Board of Medical Examiners from $10 to $20 a day during the time the board is in session.

Obituary Notes.—Dr. Henry Smith Noble, for fourteen years superintendent of the Connecticut Hospital for the Insane, Middletown, a graduate of Tufts College in 1869 and of the College of Physicians and Surgeons, New York, in 1871, and a member of the American Medical Association, the Connecticut State and Middlesex County Medical Societies, the New York Neurological Society, the American Medico-Psychological Association, and the American Academy of Medicine, died at his home in Watertown, Conn., on March 16, aged 69 years.

Dr. Lyman S. Reber of St. Louis, Mo., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1870, died suddenly at his home, on February 28, aged 68 years.

Dr. Raynor S. Freund of Butte, Mont., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1899, and a member of the Michigan State Medical Association and the Silverbow County Medical Society, died at his home from uremic poisoning, on February 26, aged 42 years.

Dr. Alexander F. Gillis of Carbondale, Pa., a graduate of the Bellevue Hospital Medical College, New York, in 1876, formerly chief surgeon at the Emergency Hospital, surgeon to the City Private Hospital, and a member of the Medical Society of the State of Pennsylvania and the Lackawanna County Medical Society, died at his home, after a long illness, on February 28, aged 66 years.

Dr. George Davidson Carl of Greencastle, Pa., a graduate of the Pennsylvania Medical College, Gettysburg, in 1855, died at his home on March 5, aged 84 years.

Dr. Thomas Elliott of Sharon, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1877, founder of the Elliott Hospital, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Mercer County Medical Society, died at the Elliott Hospital, from septic poisoning following a scratch on the thumb, on February 28, aged 59 years.

Dr. Morse L. Able of St. Matthews, S. C., a graduate of the University of Georgia, College of Medicine, Augusta, in 1890, died suddenly on February 27, aged 46 years.

Dr. James C. Hull of Providence, R. I., died at his home on March 2, aged 71 years.

Dr. Joseph Howard Raymond of Brooklyn, N. Y., professor of hygiene at the Long Island College Hospital, Brooklyn, and secretary of the Hoagland Memorial Laboratory and the Polhemus Memorial Clinic, died at the hospital after a brief illness, on March 7, aged 69 years. Dr. Raymond was graduated from the Long Island College Hospital in 1868 and from the College of Physicians and Surgeons, New York, in 1869, had served as assistant sanitary superintendent of the Departmentof Health of New York, as a member of the Brooklyn Board of Education, and from 1888 to 1903 as editor of the *Brooklyn Medical Journal,* and was the author of a textbook on physiology and of a "History of the Long Island College Hospital and Its Graduates."

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MILITARY SURGERY AND MEDICINE—SIR R. GODLEE ON ANTISEPTICS IN WAR—BOND ON GERMICIDES TO FRESH WOUNDS—HOSPITALS' FINANCES—OBITUARY.

London, March 19, 1915.

Military surgery and medicine claim our chief attention as to medical matters during the war and may possibly prove as interesting a branch of our science to you. Another hospital has been established at the front to be worked on a somewhat novel plan. Wounded or sick patients may find their way there but it is not designed for their maintenance and treatment. All such as require a considerable time of hospital care will be passed on to the base as rapidly as possible. It is to be a rest hospital for men broken down by the strain of war but who may hope that a period of complete rest and fresh air will soon render them fit to return to duty. A number of such cases are delighted to hear from the doctor that they are fit for the front again in about a fortnight. Yet there is no accommodation there for them during that time and

so they have hitherto had to be passed on to the base and some are lost for the position where they are needed and desire to be. So the rest hospital has been organized by Lt.-Col. A. L. F. Bate, R. A. M. C., commanding the Fourth Stationary Hospital. Patients are only received for fourteen days and if by that time they are not fit for duty they will be passed on. That the new hospital meets a need seems to be proved by its work in the first three months of its existence in which there were 5,852 admissions and of these 2,713 were returned to duty after an average of much less than the fortnight.

A huge factory, 150 yards long, with a glass roof and also electric lights, and heated by pipes in mid-air, close to a railway station, was taken and fitted for the hospital. The patients, as they arrive, very often in a state of exhaustion from the immediate front, requiring washing, cleaning of clothing, rest in bed, and perhaps isolation, although coming in troops at times, present difficulties to doctors and nurses which must appear insuperable to those who have only seen civil practice. A day or two may pass without much pressure but everything has to be ready to meet a sudden rush at any time.

Sir Rickman Godlee lectured at the Royal Institution on Friday last. His subject was the importance of antiseptics in war and the lesson he urged was "Back to Lister." He said many of Lister's faithful adherents had been afraid that war would bring out in relief the weak points of those who had departed from his methods. At the outset of hostilities reports reached us from the front of an almost general state of sepsis—enough to make us fear some abandonment of antiseptics must be at least in part responsible. But this was shown not to have been so, as they had been largely employed but with most disappointing results. We should not forget that military surgery was exceptional and in particular that this war was being fought under very unusual circumstances. Trenches were being dug and monster shells were being exploded in highly cultivated soil. Should they therefore throw up their hands in despair, exclaiming that it was useless to attempt to disinfect wounds to which all sorts of organisms could easily gain access? By no means, replied Sir Rickman. All Lister's work he declared cried out against such a conclusion. He still held that Lister's original method of purification by means of undiluted carbolic acid was according to our present lights the one most likely to be practically useful in the rough-and-tumble practice of the battlefield.

Mr. C. J. Bond of Leicester Royal Infirmary determined to ascertain the exact effect of strong germicides such as carbolic acid or iodine on the tissues concerned in wounds and organisms affecting them. He began some interesting observations on wounds which it seemed could not possibly be infected. For this he took advantage of post-operative wounds inflicted for the removal of varicose veins in the legs. The wound in one leg was well rubbed over with pure carbolic acid until the tissues assumed the dirty white look thus produced. In the other leg of the same patient the corresponding incision was treated with tincture of iodine B. P. In other patients out of a number of incisions on the same limb one was treated with carbolic, one with iodine, one with hydrarg. perchloride (1 in 1,000), one with carbolic acid lotion (1 in 20), others with no antiseptics. The edges of all wounds were wrapped, and all were dressed with plain white sterilized gauze, wool, and bandages.

The only difference felt by the patient on recovery from anesthesia was that the parts treated by carbolic acid smarted less than those with iodine. On changing the dressing on the second day it was not possible to decide by the appearance which way a wound had been treated. This corroborates the view of those who say that a strong antiseptic applied to an unpoisoned wound will not increase the danger, and the fact is of greater importance if, as seems reasonable, a single application of such a disinfectant has a better opportunity of dealing with invading germs than repeated washings with lotions of weaker strength.

But as soon as a pathogenic organism gains admission the conditions may be considered changed. Surgeons are repeating their testimony of the rapid improvement which follows removal of foreign bodies carried into the wound. Free drainage no doubt owes much of its efficacy to its washing away impurities which are themselves contaminated with germs. Where there is not sufficient exit the walls of a passage give shelter to organisms with the discharge, and in such circumstances it is easy to understand the benefit derived from a free dressing with a powerful antiseptic—such as will kill the germs, and if at the same time it injures or destroys portions of the tissues involved, it is worth the price. We cannot say how long after infection this treatment will be effective and as a rule we have not the opportunity of seeing the wound very soon after its infliction; nor does its appearance help us to decide whether it is too late. When in doubt apply it—it may, perhaps, be the best guide. Carbolic acid, iodine, and mercury are thought to be of about the same value, and any one at hand should be preferred to any which would take time to obtain. I do not suggest that Mr. Bond's practical teaching favors the routine use of antiseptics. What he teaches is that as we know their proper application does not affect the healing process of certain aseptic wounds, this fact should encourage the more extensive use of germicides in infected wounds at the earliest opportunity possible in suitable conditions.

The hospitals are being seriously affected by the great rise in the prices of foodstuffs occasioned by the war, amounting in some cases to from 20 to 30 per cent. A tender lately called for by St. Bartholomew's for a number of eatables was accepted for none except for milk. For this a tender for twelve months' supply was accepted but the price involves an addition to the annual average cost of £650. Other provisions will probably be bought from time to time at the market terms. It is estimated that at the prices now ruling a year's provisions would exceed the average by £4,000 to £5,000.

Sir George Turner, whose good work on leprosy and on rinderpest is well known, died on the 12th inst. in his 70th year. He entered the civil service of South Africa in 1895 and continued Koch's work. In the South African war he supervised the military hospitals and concentration camps. He devoted much time to the leper asylum at Pretoria. On returning to England he continued his studies of the bacteriology of leprosy. After several years of work in this country he contracted leprosy in the hand but continued his investigations.

Dr. Samuel Herbert Habershon, F. R. C. P., died on Feb. 26, aged 57. He was Senior Physician to the Brompton Consumptive Hospital. His father, Dr. S. O. Habershon, you may remember, was senior at Guy's Hospital. The son who has just died

was A. M. and M. D. Cantab., and elected in due course to the F. R. C. P. He has served as casualty physician at Barts' and the Royal Hospital for Diseases of the Chest. He wrote a volume on "Diseases of the Stomach" and was a contributor of many papers to the societies and journals.

4. A Study of the Efficiency of Mixed Toxins (Coley) in Inoperable Sarcoma. A Critical Analysis of 134 Microscopically Proven Cases. T. W. Harmer.

1. The Rôle of the State Sanatorium.—E. Washburn points out that the rôle of the State sanatorium is of a three-fold nature—the care and arrest of favorable cases, the education of its patients to the end that they may disseminate their knowledge of the methods necessary to prevent the spread of the disease, and the care of advanced cases, which makes possible their removal as foci of disease in their homes and communities.

2. Treatment of Pulmonary Tuberculosis.—B. T. Crane details the advantages of sanatorium treatment as follows: The disease is subtle and insidious and is not accompanied with marked bodily distress. Hence the patient is apt to overlook a backsliding in his health until it has become marked and serious, but if he is in an institution he is under the frequent observation of nurses or physicians who are trained to detect slight variations of symptoms. Regularity of routine seems to be a valuable element of treatment, and it is quite apparent that a home can rarely be systematized to operate with the precision of an institution. There is a large element of effort and task about the treatment when properly pursued. It is apparent that with the family at hand, the patient may be often excused from the effort when an institution would insist upon it. At home the patient is bound to be brought in contact with petty cares and annoyances of which he would probably be ignorant if he were away. The treatment is a tedious, long continued process, during which the fund of moral support, wise counsel and patience of a family may give out. The treatment is progressive and requires frequent alterations of orders by the physician, but if at home the patient, when feeling well, is apt to consider a visit from the physician as an unnecessary expense. Education about the disease by observation of other patients is to be had in an institution and not when taking treatment alone.

3. Mortality After Prostatectomy.—B. Tenney and H. M. Chase conclude that the greatest danger in the operation of prostatectomy is death from uremia or from conditions closely associated with it. After examining a patient one should be able to say that he is a good, fair, or poor risk with reference to this condition. If he is not put in the first class, one should try to put him there before operation, or at least get him as near there as possible. The percentage of deaths from uremia among the cases operated upon within two days was 37 per cent., while the percentage of deaths from the same cause among patients who were observed long enough to have functional tests made was 19 per cent. The second great danger in this operation is death from hemorrhage and shock. It is possible that in one's desire to avoid shock by doing a rapid operation, one may sometimes produce shock and hemorrhage by doing a needlessly rough operation. It is fair to say that a patient whose hemorrhage has been thoroughly controlled seldom starts bleeding again unless the gauze or other means of control is removed too soon. Possibly some operators have been disappointed at nature's failure to stop a leaking vessel which they had failed to close before the patient left the table. The third serious fatality is embolism, which may also be the cause for some pulmonary complications. How can one avoid at least a portion of this risk? Blood vessels are necessarily torn and left untied. The wound is in an infected region and constantly bathed in a septic fluid. A larger raw area is left exposed to this contamination than in almost any other operation. Constant irrigation does not prevent embolism. It occurs when perineal, urethral, and suprapubic drainage tubes are used and after both operations. It is possible that one's well-meant drains are responsible for some of these emboli.

1. Sex Gland Implantation.—G. Frank Lydston reviews his various contributions to this subject as follows: For hormone therapy purposes, successful total or partial implantation of human sex glands in both male and female is practicable. The prospect of success from anastomotic implantation—with resulting generative functioning—at present is not brilliant, although by no means hopeless. Glands taken from the living subject are most desirable, though rarely obtainable. Glands taken from the healthy dead body at any time prior to the beginning of decomposition are of therapeutic value equal to that of those taken from the living, if implantation succeeds. In human beings the gland of the female may be successfully implanted upon the male, and probably the reverse obtains. The hormone of the one possibly is useful to the other. The tissues of the female apparently are more hospitable to the implanted male sex glands than are the tissues of the male. The physiological and therapeutic results occur independently of the site of the implantation, but the vicinity of the peritoneum (extraabdominal) and the canal of Nuck in the female, and of the tunica vaginalis in the male, are the sites of election. Blood pressure apparently is modified, suggesting improved nutrition of the heart and vessels. The development of senility possibly can be retarded and longevity increased by internal sex secretions derived from implantation. That arteriosclerosis in its early stages will be benefited by sex gland implantation is probable. Inferentially, senile dementia, if taken early, possibly may show beneficial results. The climacteric may be postponed or at least the disagreeable features of the climacteric relieved. Defective and aberrant psychical or physical sex development and differentiation—inversions and perversions—are definite indications for sex gland implantation. Certain cases of cryptorchidism and imperfect testicular development are an especially promising field. Certain psychopathies, such as dementia præcox, possibly may be benefited by implantation. Chronic diseases of the skin, due to or modified by nutritional disturbances—notably certain types of chronic eczema, psoriasis, and ichthyosis—in a certain proportion of cases are likely to be benefited, possibly cured, by sex gland implanta-

tion. All conditions incidental to sex gland mutilations in either sex afford a positive indication for sex gland implantation, the probability of benefit being inversely as the length of time that has elapsed since the mutilation, and dependent on the age at which it occurred.

2. **Static Dislocation of the Hip.**—D. D. Ashley reports a case of this condition in a girl aged seven years secondary to extensive third degree burns which covered most of the surfaces of the lower extremities. The condition was analogous to that described by some writers in the professional beggars of India, who by holding themselves in distorted positions effect dislocations and become permanently crippled. The forces at work in such instances approach more nearly those which operated in the case described in which there was a joint capsule not weakened by disease. There was no dislocation at the time of the burn; the dislocation occurred before the child was permitted to get out of bed; one may exclude any febrile influence, as there was no considerable fever after the second week. The forces were entirely mechanical, the head being levered out of the acetabulum.

1. **Relative Frequency of Various Forms of Coma.**—W. W. Bissell and E. R. LeCount report the result of an analysis of 200 cases in which death from coma occurred in the hospital. The clinical diagnosis of skull fracture was made with relatively greater accuracy than the diagnoses of the various other causes of coma, and the greatest accuracy of diagnosis was obtained in those instances of skull fracture in which the patients died within twenty-four hours of admission. One of the noteworthy features was the frequency of the diagnosis of uremic coma. Of the fifty-three instances of cerebral hemorrhage, sixteen, or 30 per cent., were called uremia; or, to state it in another way, of the twenty-six mistaken diagnoses of cerebral hemorrhage, uremia was the clinician's conclusion in 61.5 per cent. of these errors. It has long been recognized by persons with extensive experience in the making of postmorten examinations that the diagnosis of uremia is frequently made by clinicians and rarely verified by the necropsy. Cabot has commented especally on this defect in clinical diagnosis.

3. **Cause and Treatment of Epilepsy.**—C. A. L. Reed believes that epilepsy is caused by a specific infection, probably a bacillus of the gas-forming series. The infection is located in the intestinal canal, probably primarily in the duodenum, always finally in the colon, and may be superficial, intrafollicular or interstitial; or may, and in certain cases probably does, involve the blood as a propagating medium. The infection seems to be made effective primarily through constipation of mechanical origin. The relief of the mechanical cause of the constipation with restoration of bowel function results in the cure of epilepsy in cases in which the infection is probably superficial The principle of immunization holds good in the treatment of cases in which the infection obviously lies deeper, in all of which autogenous vaccination may well be applied as a matter of routine.

5. **The Passage of Liquids from the Stomach.**—C. H. Neilson and S. T. Lipsitz find that water is emptied from the stomach somewhat more rapidly during exercise than when the subject remains quiet. Posture seems to have a direct influence on the emptying power of the stomach. Lying on the right side causes a more rapid evacuation than in any other position, and lying on the left side has the opposite effect. Lying on the back causes a somewhat more rapid emptlying than in the upright position. At 45° C. water leaves the stomach somewhat more rapidly than at 10° C. Normal acidity causes a more rapid emptying than hyperacidity produced artificially by adding hydrochloric acid to the stomach contents. Artificial alkalinity produced by adding sodium bicarbonate to the stomach contents causes the stomach to empty itself slightly less rapidly than under normal conditions, but more so than during hyperacidity. All of these factors may have considerable significance in their bearing on clinical experience.

6. **Streptococci from Pyorrhea Alveolaris.**—T. B. Hartzell and A. T. Henrici have shown that streptococci of the viridans group are constantly present in peridental suppurative lesions. This is not surprising, since such streptococci are normally present in the saliva and on the buccal mucous membranes. These streptococci are normally of low virulence, but are at times able to produce lesions of the heart, aorta, kidneys, and joints, some of which closely resemble the lesions of rheumatism; that they are potentially of high virulence is shown by the experiment in which they were grown in the anterior chamber of the eye. One cannot claim, from the evidence so far obtained, that these streptococci bear an etiologic relationship to dental abscesses and pyorrhea, but from the point of view of metastatic infections it is important to know that such organisms are constantly present in lesions presenting a large ulcerated surface, through which they may, and probably do, frequently pass into the deeper tissues and the blood stream.

2. An Outbreak of Toxic Jaundice due to Tetrachlorethane Poisoning. A New Type Amongst Aeroplane Workers. W. H. Willcox.
3. Surgical Notes on Serious Head Injuries. (From an Evacuation Hospital, British Expeditionary Force, France.) A. G. Whitehorn-Cole.
4. An Unusual Rupture of the Mitral Valve. A. M. Kennedy and J. B. McDougall.

1. **Operative Treatment of Cleft Palate.**—H. Blakeway concludes that Langenbeck's operation is still the best for routine use. The question as to the best age for its performance does not admit of precise answer. It is doubtful if any great advantage results from performing it during the first year of life, and it is certain that the prospect of success during the second or third year will often be better. Further delay is not usually necessary, but may in bad cases be advisable. Surgeons who a few years ago were content to operate in the third year or later now often perform median suture on children one or two years old. The experience of the

operator, the width of the cleft, together with the height of the palatal arch and the general health of the child, have all to be considered before a decision is reached. If the condition is complicated by the presence of a harelip, closure of the latter during the first few weeks of life has a valuable effect in causing obliteration of the most anterior part of the cleft.

2. **Toxic Jaundice among Aeroplane Workers.**—By W. H. Wilcox. (See page 612.)

3. **Serious Head Injuries.**—A. G. Whitehorn-Cole reports a series of cases from one of the British base hospitals. These cases illustrate the large amount of injury sustained by the bony skull and underlying brain tissues; also the enormous amount of brain injury and destruction which can take place, and yet the patient may recover to an almost normal condition of life and intelligence, and in a compaartively short time. The author has had the opportunity of seeing a very large number of head injuries, the results of rifle and shrapnel bullets, and the procedure which he invariably adopted was that of carrying out the minimum amount of surgical interference compatible with the injuries. In those cases in which the bullet was deeply lodged in the brain substance it was considered inadvisable to search for it, since the further laceration of the tissues engendered by the process would be more injurious to the patient than the foreign body itself. Before proceeding to operate the head was entirely shaved, under the anesthetic, then thoroughly cleansed with ether soap, then washed with alcohol, and finally painted with iodine. All these cases took the anesthetic remarkably well, never showing any bad after-effects, viz., vomiting, etc. The anesthetic usually employed was chloroform and ether.

4. **Rupture of the Mitral Valve.**—A. M. Kennedy and J. B. McDougall report a case of malignant endocarditis occurring in a man sixty-one years of age. The process was not valvular but mural, in which the inflammatory reaction in the cardiac tissue at the base of the mitral valve was so acute that necrosis occurred and the cusps were torn off from their attachments to the wall.

1. **The New Psychiatry.**—W. H. B. Stoddart devotes the first of the Morison Lectures to the theme of fundamental psychical mechanisms. In order to understand the principles of abnormal psychology it is necessary to gain a clear conception of human instincts. To those of self-preservation, nutrition, and sex there has recently been added a fourth instinct—that of gregariousness, the herd instinct of Trotter. There is a constant play between the instincts, one giving place to another as occasion arises; but when a herd impulse becomes displaced by the driving force of some other instinct mental conflict ensues; there is a situation to be faced, and a way out of the difficulty must be found. The conflict may be resolved in one of four ways: First, the influence of the herd instinct may be recognized and its influence voluntarily ignored, the delinquent avowing to himself that he has a perfect right to do as he likes. Secondly, the offense may be condoned by "rationalization." Thirdly, the emotional tone or effect of worry may gradually pass off as years roll by. Lastly, the incident may refuse to become assimilated to the existing content of consciousness, and is repressed into a department of mentation from which it can never again enter phenomenal consciousness and disturb the normal stream of associative thought. The conception of the unconsciousness is one of the fundamental bases of the Freudian psychology. Another fundamental doctrine is that of "psychical determinism." A complex is defined as a repressed system of ideas having a constant conative trend or emotional tone and directed toward determinate actions and thoughts. When there develop in the mind two complexes which are out of harmony with each other conflict ensues. The majority of conflicts are between a sexual and a herd complex.

3. **Treatment of Emphysematous Gangrene.**—J. B. Haycraft believes from the nature of the disease that most hope is to be expected from prophylactic rather than curative treatment. Unfortunately it is impossible, for military reasons, to "get at" these wounds within an hour or two of their reception, but much may be done by vigorous treatment at the earliest possible moment, followed by a careful watch on each case. Strong antiseptics should be used in wounds unless obviously infected, when hydrogen peroxide will prove most beneficial. Conservative methods should be tried as much as possible, more especially where baths can be employed; if, however, they are not possible, as in bad infected compound fractures of the thigh, then amputation should be resorted to without delay.

8. Cerebrospinal Meningitis; Diagnosis and Prophylaxis. A Lundie, D. J. Thomas and S. Fleming.

1. **Oral Sepsis.**—H. L. McKisack states that this condition is sometimes tolerated by the patient for many years with little apparent injury. It is always a possible source of danger. It may give rise to disease in the vicinity of the mouth; disease in situations which come directly in contact with the unhealthy secretions of the mouth, such as the stomach and the intestines; disease in distant parts of the body not in direct communication with the morbid secretion, and a state of ill health and lowered vitality without obvious involvement of any organ. It may thus be said to aid and abet disease arising from some other source. It is commonly the result of imperfectly cleansed teeth. It does not necessarily involve the extraction of teeth.

2. **Treatment of Diabetes with Casein and Cream.**—R. T. Williamson, in carrying out this treatment, gives casein and cream in small quantities every two hours. The patient is kept at rest in bed, or on the sofa, and every two hours, from 8 A. M. to 10 P. M., receives a glass of artificial milk prepared from casein, cream, and water. One tablespoonful of casein is well mixed in a tumbler with one tablespoonful of cream until a paste is formed; then hot water (or cold if preferred) is added gradually until the tumbler is full, the mixture being well stirred with a teaspoon whilst the water is being added. A white fluid is thus prepared which has the appearance of milk. It contains milk albumin and fat, but only a very small percentage of milk sugar derived from the cream. The fluid may be sweetened with saccharine if desired, or a pinch of salt may be

added, or it may be flavored with nutmeg, according to the patient's taste. Most patients prefer the fluid warm. Usually the patient takes this artificial milk quite well, and likes the taste; some take it well, but do not find the taste quite satisfactory; but a few patients complain that it causes nausea, and in such cases it should be at once discontinued. The fluid may be taken well when it is hot, but may cause nausea when lukewarm or cold. When it produces nausea, or is distasteful even when the fluid is warm, another preparation of casein should be tried. 1. This method will often remove the sugar from the urine when the ordinary rigid diabetic diet has been unsuccessful, and this is its great value. 2. The results are often prompt, the urine being free from sugar after two or three days. 3. After a period of treatment with casein and cream the patient is often able to take ordinary diabetic diet, or even a less rigid diet, without the appearance of sugar in the urine, whilst previous to the casein treatment the most rigid diabetic diet did not remove the sugar from the urine. 4. Though the sugar will return in the urine in course of time in most cases after the patient's diet has been relaxed, the return is much less rapid than when the sugar has been removed from the urine by an ordinary rigid diabetic diet. 5. The casein method is not expensive and is easily carried out. 6. In most cases of the very severe forms of diabetes in which the urine contains much diacetic acid the casein treatment is of little value, and sometimes may be very unsuitable; still in certain cases it is of much service, and may remove the diacetic acid and even the sugar from the urine for a short time, and on returning to a less rigid diet the sugar excretion may be very small for a long time and the diacetic acid may not return for a long period. Such cases form only a minority of the cases of this class.

3. **Vaccine Treatment of Pneumonia.**—W. H. Wynn regards 100 million killed pneumococci as a suitable initial dose in an average adult man. In women and the less robust 50 to 75 million may suffice; 25 million is certainly too small a dose, and even when given during the first twenty-four hours rarely has that definite effect in cutting short the fever which is seen with larger doses. When a dose of 100 millions has no effect upon the symptoms the next dose should be increased, injections being given every day until an effect is obtained. When a definite improvement has followed the first dose, the next should be given in forty-eight hours. It is advisable to continue the injections until the lungs have completely resolved. Sir A. E. Wright, in his recent work on the use of vaccines in pneumonia, found that inoculation in the form of small doses frequently repeated was absolutely ineffective, and that, on the other hand, inoculation in the form of a single large dose, administered in the incubation period, often arrested the disease and averted death. He thinks it reasonable that the results obtained during the incubation stage with doses of 250 to 1,000 million would repeat themselves if this treatment were applied in the early stages of pneumonia.

4. **The Action of Calcium Salts.**—C. O. Jones concludes that: 1. Calcium salts, when injected into the blood in small quantities, are excreted by the kidneys as phosphates, carbonates, and oxalates. 2. In larger quantities the bowel also takes part in the excretion, and the calcium is excreted as inorganic salt. 3. At a fixed concentration of calcium in the blood greater than the above, the kidneys are thrown out of action and all the excretion is performed by the intestine, until a point is reached where the quantity in the blood is again brought below the "toleration point," when the kidney again takes on its excreting function. 4. If the concentration in the blood is greater still, the calcium is excreted also as calcium soap by the intestine. 5. The excretion of large quantities of calcium through the intestinal walls has an astringent action, and causes diminished action and paresis of the intestinal movements. The feces cease to be excreted so freely, and if more calcium arrives in the blood the increased concentration of the calcium ion produces spontaneous intravascular clotting and death. 6. The calcium "toleration point," or the point of concentration of calcium in the blood above which the kidneys are unable to act, can be raised by injecting increasing doses of calcium chloride into the blood, provided time is given for the animal to complete the excretion of one injection before the next is given. This action appears to extend the theory of immunity into the inorganic world, and shows that the body can react to calcium salts much in the same way that it reacts to an organic toxin.

6. **Eye Injury from Bursting Golf Ball.**—R. H. Elliot and W. S. Inman note that the accidents of this nature that have been reported have all been due to the balls being cut open. The dangerous balls are the fluid core balls containing a mixture of barium sulphate, soap, and a free alkali. The core is surrounded by machine-wound indiarubber ribbons and is thereby subjected to great pressure. When the ball bursts or is cut open the contained fluid is expelled with explosive force. A review of the recorded cases shows the following points of interest: 1. The damage done is of a very serious nature; thus of the four cases reported on at length by Lowell three lost the use of one eye; Crigler's case only retained the power of counting fingers at one foot; the final vision in Thomason's case was 2/3, in Jessop's only 6/60, and in Gravely's case perception of light, and even that doubtful. In the present case it is limited to the power to distinguish hand movements only. 2. The seriousness of the loss is more fully appreciated when one takes into account that a large percentage of the cases are in children or young people. 3. In at least two of the recorded cases the victim of the eye injury was not the person who was opening the ball, but an unfortunate child who was looking on.

Color Analysis of Bread.—Posner showed as far back as 1898 that various kinds of nutriment are susceptible to tinctorial analysis, even with the naked eye. Thus with certain stains starch granules were not colored, bran took one stain while gluten took another. These finds remained unnoticed and passed into obscurity, although similar efforts by subsequent writers received a perfunctory mention in the text books of the period. Since the war began the author has resumed his studies by reason of the opportunities for falsification

over and above permissible requirements. Thus, given the opportunity for mixing wheat flour, rye meal and potato meal in certain proportions dealers could readily vary the limits allotted. Naturally there sprang into existence an independent effort on the part of the Governmental authorities to check abuses, and wheat flour, potato flour, etc., have received separate microscopic study, with and without staining methods. The results agree quite closely with those of the author. Thus if a little rye meal is shaken up with water, colored with Giemsa stain, repeatedly sedimented or centrifuzed and then washed clean the sediment, enlarged 90 fold, shows for each field a certain count of starch granules, bran cells and masses of gluten; while fine wheat flour shows much smaller starch granules in a similar count, a slight residue of bran and rather more gluten. If a section of potato is magnified we see bran cells closely stratified on the periphery and beneath these starch cells in abundance, some filled with starch granules. In all cooked starch the cells undergo the characteristic change to starch paste, undergoing enlargement and denaturization. In all starches and cereals, flours or meals are made of both raw and cooked products, and we therefore have two species of potato flour readily distinguished under the microscope without staining. However, difficulties arise chiefly after bread is baked. The so-called "war bread" can be cut in sections, stained and studied under dark field illumination and the relative proportions of starch, brans, and gluten can be made out. In addition it is possible to distinguish between rye starch and potato starch. The cells of the latter are larger, especially after boiling. The mistake, however, must not be made that bran is necessarily digestible. The larger cells not only are rich in indigestible cellulose but the latter also prevents some of the gluten from attack by the digestive fluids. In certain subjects this cellulose antagonizes constipation, while in others it is an irritant.

Individual Observations on Tetanus in Peace and War.—Grundmann has seen numerous cases of tetanus in the Rudolf-Virchow Hospital, Berlin, in past times, and since the outbreak of the war has seen 25 military cases. He finds it a law that the nearer the wound site to the central nervous system the shorter the incubation period. In figures the incubation period lasts from 3 to 14 days. His initial symptoms comprised spasm of the esophagus; marked sweats; slight shock from noises, light and air draughts; vertigo; twitching, rigidity, and overexcitability of muscles (especally upon percussion. In regard to prophylaxis, immunizing injections have to be renewed every two weeks. It is stated on authority that under the preventive use of antitoxin not a German soldier developed the disease in the Boxer campaign in China. Under treatment the author lays the greatest stress on nutriment. Patients should be fed hourly with addition of concentrated nourishment. The intense, persistent muscular contractions load the blood with katabolic products, which cannot be completely excreted; and the older narcotics, which were curative at times, antagonized this excretion. The newer magnesium sulphate does not possess this disadvantage. This salt is antagonized physiologically by calcium chloride and physostymin. In regard to prognosis and treatment: anticipating the statement as authenticated that in all cases with less than eight days' incubation the mortality is 90 per cent., the author in saving several lives in this class, has reduced the mortality to 80 per cent. The author's total mortality was 65 per cent.—or after deduction of moribund cases 55 per cent. Before the author had assumed charge of his field hospital the mortality had been 100 per cent.

Münchener medizinische Wochenschrift.

February 23, 1915.

War-Medicine Experiences in England and France.—Professor Madelung attempts a study of the surgery of the allied armies, with a view in part of dealing with the effects of German projectiles. He asks what are the effects of the German small arms projectiles as to course of healing, development of tetanus, and gas phlegmous? What of the spread of typhoid and dysentery and of the value of prophylactic medication? The German military surgeon would like to read the experiences of his French colleague, and *vice versa*, but this is of course out of the question. As far back as July 1, 1914, all interchange of experience of this character has been abrogated; and since August 1 any comity among medical men has entirely ceased. Therefore the Germans have had to depend largely upon the medical publications of neutral countries for details of medical advance which result from the war. But here we find the same difficulties. For the Boston *Medical and Surgical Journal* in September, 1914, and the *Policlinico* of Rome in the following October complain that all their foreign news service is greatly curtailed. The author has been forced to make use of various North American medical journals which publish European letters. Naturally he uses only the actual data, stripped of their partisan (to him) coloring. From the current reports of the Department of Health of New York he extracts statistics of birth rates which tend to show why Germany can put so many young men in the field.

Healing Processes in Natural Pneumothorax.—Rieder has studied these with the aid of *x*-rays. Our knowledge of natural pneumothorax has increased owing to the study of artificial pneumothorax. We can understand how apparently healthy subpjects can go about with pneumothorax and seldom consult physicians for it. The condition comes about from increase of intrathoracic pressure, most commonly from expiratory spasms, as in violent sneezing, laughing and coughing; and less frequently from inspiratory efforts, as in rapid cycling, lifting a heavy load, etc. Forced breathing, however, is unable to rupture a sound lung in animal experiment. As a rule the pneumothorax causes sharp pain and dyspnea. But in certain cases these symptoms are not marked and may even be absent. These cases of natural pneumothorax are usually dry and then may heal spontaneously, even in a tuberculous lung. As a matter of fact tuberculosis is almost always suspected in these cases, even if the subject seems in perfect health. In other cases asthma and emphysema are in evidence. In pneumothorax with slight exudation the latter may become absorbed. The secondary formation of an exudate, such as is so commonly seen in artificial pneumothorax, is usually a good prognostic for spontaneous recovery. Whenever large inflammatory exudates form, the question of recovery is more problematical and this holds good for extensive seropneumothorax. A pulmonary fistula forms in some cases of rupture of a cavity into the pleura and the air is spontaneously absorbed. Most commonly spontaneous recovery is due to closure of a small tear, either by ordinary repair or by adhesion formation. In a closed pneumothorax in which absorption is delayed, aspiration of the thorax stimulates the process. It is naturally of great importance to know if we are dealing with an open or closed pneumothorax. The latter can be present only if the following symptoms are *absent:* fistula sounds on auscultation; inconstant radiograms; overpressure in the pleural space (there is usually slight negative pressure); positive symptoms of any kind. Closed pneumothorax is also rare.

Insurance Medicine.

THE GENERAL FACTORS DETERMINING MEDICAL SELECTION.

FROM "ALLGEMEINE LEBENSVERSICHERUNGSMEDIZIN"

BY PROF. DR. GEORG FLORSCHÜTZ OF GOTHA.

(*Continued from page* 582.)

LIFE insurance medicine grasps with the eye the person of the applicant as a whole and judges in the first place according to the general impression. But it never relies on the bare judgment of the examining physician, and demands an exact appreciation of the habitus through the most careful body measurements. Not the subjective impression, but measure and figure are the cornerstones upon which life insurance erects its conception of the constitution; and these must in all cases supply the frame within which the medical examiner records the knowledge acquired by clinical investigation and transmits to the medical director the picture of the complete somatic constitution.

But little as life insurance medicine is able to unveil the ultimate foundation of things, or to succeed even in the empirical establishment of the existence of definite facts, just so little can it solve by the aid of statistics the second of its principal tasks, viz., the correct estimation of heredity in its biological sense. The confines are even narrower here than in the first problem. It pursues neither breeding experiments nor embryological studies, and can therefore contribute nothing to the question which occupies the first rank in biology, "how and through what is anything inherited?" It can only show by comparison that in a definite family with definite stigmata, a morbid event appears more frequently than in another family without such stigmata. But with this proof it is perfectly satisfied. It is not necessary to bother about the why, and least of all to throw oneself into the arms of theories; for with proof of the fact of the existence of hereditary relationship, the question of inheritance, as far as life insurance is concerned, has been practically decided.

Naturally life insurance does not for an instant undervalue the extraordinary importance which the biological achievements of recent times possess in themselves, and takes account of them as far as possible in its investigations. The main point, however, remains always for life insurance, that it so sharply grasps the characteristics which lie at the base of its investigations that in the final result only the hereditary influence actually remains, and not other factors which come to expression, which would render the entire investigation illusory.

Life insurance rests here quite upon the standpoint of Cornet, when he allows only such statistics to hold good as proof of the heredity of tuberculosis as proceed from a material in which the possibility of an infection has been excluded. For as tuberculosis can doubtless appear cumulatively in a family, not because it is inherited but because it is contagious and the family lives in unfavorable hygienic conditions which favor infection, so also in other investigations, other factors could place in question the correctness of the results. If, however, the investigations have been carried out after strict sifting of material and have led to a positive result, life insurance is also justified in regarding the matter of inheritance as settled and in including heredity as a certain factor in its prognostic calculations, even if the biological delving is not yet so advanced as to demonstrate *ad oculos* the why and wherefore of heredity.

Now, indeed, one no longer regards statistical investigations as of little value, since through Lorenz the catch-word "mass of inheritance" has come into use and one believes it possible to explain or understand posterity only through massed observations of numerous generations. Life insurance has therefore been reproached as being quite without authority in questions of inheritance because, as a rule, the data of certainty obtained from applicants for insurance do not go beyond the parents. But this reproach hits all statisticians who in the make up of their material must rely upon the memory of mankind, which, as a matter of fact, seldom goes back with accuracy to the grandparents. Life insurance companies, however, are not in this class, especially the longest established among them, for to-day they often insure the third generation of the same family and hence control a material than which nothing can be more certain for heredity investigations. Equally baseless is the further objection that has been raised against heredity investigation by life insurance companies that in young applicants whose parents are likewise still young the companies cannot state the actual degree of hereditary taint, because they do not know whether the parents will die of inherited disease, especially when the latter belongs to those affections which appear only in advanced age. This objection would be justified if the companies used such cases as their investigations; but, fortunately, their material is so great that they can throw these out entirely.

What results have the investigations by life insurance companies thus far established? Among all life insurance statistics in Germany none have been more frequently used or are regarded as more reliable than the jubilee statistics of the Gotha Life Insurance Bank from the year 1879. We extract therefrom the following table, which gives information as to the course of the mortality from tuberculosis, chronic diseases of the brain and cord, mental affections, heart disease, and cancer, with a history of the same diseases as causes of death in the families of the deceased.

During the period 1829-1878, inclusive, there died the following insured in whose families the same cause of death had been in evidence:

Percentage of Deaths From	Risks with Family History of				Percentage of All Insured Who Died of these Diseases
	Tuberculosis	Chronic Brain, Cord and Mental Disease	Heart Disease	Cancer	
Tuberculosis	23.7	10.3	10	10.5	11.63
Chronic brain, cord, and mental disease	4	11.3	6.4	3.4	4.15
Heart disease	5	6.2	12.9	5.1	5.81
Cancer	4.1	7.2	4.2	9.3	5.01

The table teaches that the mortality from tuberculosis among the insured who were tainted hereditarily with tuberculosis was twice as large as the average mortality of all the insured from tuberculosis; and that, measured with the same measure, the outlook for death from mental diseases for those tainted therewith was almost thrice as large; for those tainted with heart disease, twice as large. Hence, there must have been something which con-

ditions among the tainted a cumulation of deaths from the same cause. This "something" we term, in brief, heredity. That the diseases are not inherited *per se*, but only in the form of a predisposition, has been determined beyond doubt by biology. Certain qualities of the body, a special type of somatic constitution, must be inherited, which as a predisposition exposes posterity to the expectancy of the same diseases from which the forefathers perished. Whether this preparedness for disease is to be regarded as a general affection of the protoplasm (Ebstein) or as a functional inferiority of definite organs and organ systems (Martius) may be left undecided. For us the one important question is "Can we recognize this predisposition so surely before the appearance of manifest symptoms of disease that we can reject the endangered applicant, or according to the degree of hazard accept him as a substandard and at a higher risk?

And here the same statistics give a very distinct hint. They show further that while the tuberculosis mortality in the tainted had been doubled, it jumped up to threefold (34.9 per cent.) if one isolated for examination such risks as had shown upon acceptance a more or less pronounced habitus phthisicus. This result must surprise us the more because special attention had always been paid to this habitus on acceptance and it had always been believed that in rejecting the classical cases due heed had been paid to the principle of selection. Yet errors must have been made and therein lay the reason for the so notably increased mortality from phthisis.

What these errors were cannot be told off-hand, but it is certain that only through recognition and rejection could a reduction of tuberculosis mortality be expected. My own investigations soon taught me that one could have drawn the conception of the habitus phthisicus too finely; that is, one had believed it to be quite sufficient to reject only those characterized by abnormally long, narrow, and shallow thoraces, with acute epigastric angle, great width of intercostal spaces, and slight diameter.

At the Second International Congress of Insurance Physicians, held at Amsterdam in 1901, I first reported on my investigations. Laying emphasis on the then still strongly opposed viewpoint that the disease substratum is the sole conception about which all revolves in the question of insuring the tuberculous, I indicated the emaciation, the undernourishment of the organism as the disease substratum of tuberculosis, because the organism is thereby deprived of its resistance against the exciting causes of disease.

A "something" which cannot be strictly defined is lacking in this organism, and because of this lack the organism becomes an excellent culture medium for the tubercle bacillus. It is not our task to probe the nature of this "something," for we need only to recognize betimes this insufficiency in the individual; but this task is especially difficult, for not all thin subjects can be regarded as lacking simply because they are thin. We have to consider here, above all, the family habitus, occupation, mode of life, athletic training, all of which may co-operate strongly. Nevertheless a threatening emaciation can be recognized through the fact that advancing years do not improve conditions in the least, although an increase in weight is physiological.

I continued my investigations in the following years, and first of all imposed upon myself the task of seeking for a procedure which would enable one to comprehend and express objectively the inferiority of these organisms; for only in this manner would I expect to obtain an unobjectionable basis for investigation. In this procedure I depended upon the measurements of the individual, and under the "constitution" of an applicant I understood in every case such quality as could be expressed objectively by taking the height, chest measure, abdominal girth, and by recording the weight. Upon this foundation I built further and laid out in detail the course which the investigation has taken.

(To be continued.)

The Relation of Sickness Insurance to Public Health and the Common Welfare.—"The object of sickness insurance is to distribute the loss due to sickness and death over the community according to responsibility. This will automatically make those responsible search for and enforce measures to prevent sickness and death." These were the opening words of a paper read before the American Public Health Association by Dr. B. S. Warren, surgeon, U. S. Public Health Service. The paper points out that at present, in the United States, the burden of this loss is borne by the individual who, in many instances, is broken by the extra load and is added to the number of impoverished or destitute to be cared for by the community. Experience in the field of sickness insurance shows that the following provisions are necessary to the success of any plan: (1) It must be compulsory, especially for those with small incomes. (2) Cash benefits not to exceed 66 2/3 per cent. of the wages for a period of not more than 26 weeks in one calendar year. (3) Invalidity benefits elastic in character. (4) A small death benefit sufficient to meet the ordinary expenses of burial and other immediate necessities. (5) Medical benefits to include medical and surgical relief in home, hospital, or sanatorium, as necessary, and medicine, appliances, and specialist service, including denistry. The following plan relative to contributions, is believed by many to be the most equitable: (1) The funds to be provided by contributions as follows: Insured persons, 50 to 66 2/3 per cent. Employers 33 1/3 to 50 per cent. Community or State 10 to 25 per cent. (2) The amount of weekly contributions has not been very definitely determined but it is believed that a total of 50 cents per person per week from all sources will provide the following: (*a*) $1 per day for disability due to sickness and nonindustrial accidents, to begin on the fourth day and not to exceed 26 weeks in one calendar year. (*b*) $200 death benefit for deaths due to sickness and non-industrial accidents. (*c*) Adequate medical and surgical relief. (3) Provisions must be made for changing the amount of contributions from year to year to adjust the funds to the hazards of the industry and prevent the accumulation of an unusual surplus or deficit in any fund. On questions of administration there does not seem to be much difference of opinion as to the following provisions: (1) The administration must be democratic, and employees must have a voice in the control in proportion to their contributions. (2) The insured persons must have a feeling of ownership and responsibility for the proper conservation of the funds. (3) An efficient medical service must be provided and closely related to the public health authorities, so that the clinical and preventive medical benefits may yield the best results.

Book Reviews.

Operative Surgery of the Nose, Throat, and Ear for Laryngologists, Rhinologists, Otologists, and Surgeons. By Hanau W. Loeb, A.M., M.D., Professor of Ear, Nose, and Throat Diseases in St. Louis University. In Collaboration with Joseph C. Beck, M.D., R. Bishop Canfield, M.D., George W. Crile, M.D., Eugene A. Crockett, M.D., William H. Haskin, M.D., Robert Levy, M.D., Harris P. Mosher, M.D., George L. Richards, M.D., George E. Shambaugh, M.D., and George B. Wood, M.D. In Two Volumes. Volume I. Four Hundred and Nine Illustrations. Price, $6.00. St. Louis: C. V. Mosby Company, 1914.

The title of this work accurately describes its scope, which includes strictly the operative surgery of the nose, throat, and ear without any discussion of pathology, etiology, or symptomatology. The first volume deals with the surgical anatomy of the nose, throat, and ear; the external surgery of the throat; the direct examination of the larynx, trachea, bronchi, esophagus, and stomach, and the operations made possible through its agency; and the plastic surgery of the nose and ear. The illustrations constitute a conspicuous feature of this work, both in their artistic excellence and in their clear elucidation of the text. As an up-to-date treatise in its special field this work is perhaps unique in the English language. In its mechanical features it stands for the best in the publisher's art.

Orthopædics Indispensable to Practitioners: by F. Calot, Head Surgeon at the "Hôpital Rothschild, Hôpital Gazin, Hôpital de l'Oise et des departements, Dispensaire, Institut orthopédique of Berck," etc., with 1252 Original Figures and 8 Colored Plates. Translated from the 6th Edition in French by A. H. Robinson, M.D., M.R.C.S., and Louis Nicole. Price, 21 Shillings. London: Bailliére, Tindall and Cox, 1914.

In one large volume of 1132 pages of reading matter the writer sets forth, largely by means of questions and answers, his views on some of the more common orthopedic affections, and urges the necessity of early treatment by the general practitioner. He advocates strongly the use of injections, of sea air, and of plaster of Paris in joint tuberculosis, and warns strenuously of the dangers of converting by operation a closed tuberculosis into an open one. In young or old his treatment is always conservative. His plaster of Paris technique is very beautiful. A comparison of the chapter on joint tuberculosis with the recent books of Rollier and Fraser on the same subject is very instructive. All set forth different conclusions. Each author reaches his conclusions from clinical experience.

Calot's book includes chapters also on tuberculosis of the lymph nodes, skin, testis, etc., and a chapter on certain fractures. The treatment recommended for tuberculous adenitis is also conservative. The book is illustrated profusely and well, and contains an excellent index. Its style is somewhat colloquial, its English is at times peculiar, and it bears the ear-marks of French printing and publication. Although the author is perhaps somewhat over-enthusiastic along certain lines, he has put into his book much practical information, and the reader can derive instruction from it on many technical points. It is doubtful, however, if the large amount of knowledge it contains is really indispensable to the general practitioner.

Laboratory Manual for the Detection of Poisons and Powerful Drugs. By Dr. Wilhelm Autenrieth, Professor in the University of Freiburg i. Br. Authorized Translation of the Completely Revised Fourth German Edition by William H. Warren, Ph. D., Professor of Chemistry in Wheaton College. With 25 illustrations. Price, $2. Philadelphia: P. Blakiston's Son & Co.

This volume is not intended for a medical textbook. Perhaps a third or more of its contents deal with this one aspect of medical toxicology, but these pages are practically all in fine print. The bulk of the volume deals with the detection of toxic food adulterations, the detection of minute amounts of poisons as natural or accidental impurities, and with other conditions of purely chemical significance.

The translator has incorporated into the work the very latest methods for the detection of certain poisons. Although intended as a laboratory guide the book should be of value to the physician for reference purposes.

Morris's Human Anatomy. A Complete Systematic Treatise by English and American Authors. Edited by C. M. Jackson, M.S., M.D. Eleven Hundred and Eighty-two Illustrations. Three Hundred and Fifty-Eight Printed in Colors. Fifth Edition, Revised and Largely Rewritten. Price, $6. Philadelphia: P. Blakiston's Son & Co.

This volume maintains the arrangement of the preceding edition, consisting of thirteen sections. The personnel of the contributors has undergone great changes. The editor has personally revised the section on Morphology; F. Wood Jones has revised that on Articulations; H. D. Senior has performed the same service for the Blood vascular System, and Eliot R. Clark for the Lymphatic System. Others who have revised sections for the present edition are as follows: D. Waterston, Special Sense Organs; the Editor, Digestive System; A. T. Kerr the Skin, Mammary Gland, and Ductless Glands. Clinical and Topographical Anatomy is handled by John Morley. In other words eight sections have been thoroughly revised and some largely rewritten by the new contributors. In the other sections the contributors are those of the preceding edition. Not one of the contributors of the third edition (1902) remains. The American contributors to the fifth edition are Jackson (the editor), Bardeen, Senior, Clark, Hardesty, Terry, and Kerr. If to these we add the Canadian contributor McMurrich, we note that eight of the twelve contributors are from the Western Hemisphere. Contributors to the earlier editions have been overwhelmingly British.

Another no less striking departure is in the personnel of the contributors. In the earlier editions (and this holds good for most anatomies) the contributors were chiefly prominent surgeons. In the present volume every man is a professed anatomist and histologist and member of his National British or American Anatomical Society. It may perhaps suffice to say that such a work is admirably conceived and executed.

Local and Regional Anesthesia. With Chapters on Spinal, Epidural, Paravertebral, and Parasacral Analgesia, and on other Applications of Local and Regional Anesthesia to the Surgery of the Eye, Ear, Nose and Throat, and to Dental Practice. By Carroll W. Allen, M.D., Instructor in Clinical Surgery at the Tulane University of New Orleans; Lecturer and Instructor in Genito-Urinary and Rectal Diseases at the New Orleans Polyclinic; Visiting Surgeon to the Charity Hospital. With an Introduction by Rudolph Matas, M.D., Professor of General and Clinical Surgery at the Tulane University of Louisiana, New Orleans, etc. Octavo of 625 pages with 225 illustrations. Price, cloth, $6.00 net; half morocco, $7.50 net. Philadelphia and London: W. B. Saunders Company, 1914.

This is the largest and most pretentious of the many books on this subject that have appeared during the past few months. From the preface and elsewhere we learn that Matas had originally intended to write a book on local anesthesia, but found that he could not devote sufficient time to the preparation of the work and had practically given up the idea when his assistant, Dr. Allen, offered his collaboration. Matas soon found, however, that he had no time to assist in editing the mass of material collected by Allen, so turned over his own material to Allen, who has thus proceeded alone in the compilation of the book. We say compilation advisedly, for the book consists of a curious mélange of original observations and far more extensive quotations from the writings of Matas, Crile, Cushing, Braun, Härtel, Fischer and a host of others. Quotations often cover many consecutive pages, while short quotations are found so frequently that Allen's original work is almost lost sight of altogether in some portions of the book. It must be said, however, that by pursuing the policy of direct quotation the work assumes an authoritative character that it could not have otherwise and also that about every phase of the subject is covered with a wealth of detail.—so much so as to be almost bewildering at times, and to suggest the wisdom of considerable condensation when the demand arises for a second edition.

Among the special features of this book, in addition to those enumerated on the title page, are: chapters on the nerves and their sensations, toxicology, shock, anoci-association, and a most complete consideration of the various agents that have been used in the production of local anesthesia and the methods of using them, including intra-arterial and intravenous injection.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 18, 1915.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Medicine. The program was furnished by the staff of the Rockefeller Institute of Medical Research.

Numerical Laws Governing the Rate of Excretion of Urea and Sodium Chloride in Health and Disease.—Dr. FRANKLIN C. MCLEAN read this paper. He stated that the laws governing the rate of excretion of urea and sodium chloride in the normal individual, as formulated by Ambard and Weill (*Jour. de Phys. et Path. Gen.*, 1912, V, XIV) had been confirmed by numerous observations on healthy subjects. (See also, McLean and Selling, *Jour. of Biol. Chem.*, September, 1914.) To express the relative ability of the abnormal individual to carry on the function of urea excretion an "Index of Urea Excretion" had been formulated, based on the concentration of urea in the blood and the rate of its excretion. The average normal index was expressed as 1.00 or 100 per cent., and deviations from the normal were expressed in their percentage relationship to the normal. An index of 0.25 or 25 per cent. for example, indicated that the individual was excreting urea at a rate that was 25 per cent. of the normal, when the actual rate of excretion was compared with the concentration in the blood. The excretion of sodium chloride was similarly measured, by comparing the concentration of chlorides in the plasma with the concentration calculated from the rate of excretion. In normal individuals the actual amount found did not vary more than 1 per cent. from the calculated amount, while considerable variations might be found in the abnormal individual. The two important functions, which might be quite independent of one another, were thus measured simultaneously, without requiring the ingestion or injection of any foreign substance, and without requiring any control of the intake of nitrogen or chlorides. Rapid and accurate methods were now in use for all of the estimations, and the calculations necessary had been rendered simple by the use of a calculating device in the form of a modified slide rule.

Epidemiology of Pneumonia.—Dr. DOCHEZ presented this paper in which he said that a study of pneumococci isolated from individuals suffering from lobar pneumonia had shown that the majority of these organisms fell into definite biological groups. These groups had been arbitrarily numbered from I to IV. An analysis of 150 cases of pneumonia showed that Type I of the organism was found in 57, or 38 per cent. of the cases; Type II was found in 44, or 30 per cent. of the series; Type III (mucosus) was found in 17 or 11 per cent., and Type IV (heterogenous) was found in 32 or 21 per cent. The first three groups consisted of organisms which within the group were closely related to each other by certain immunological reactions, namely, protection and agglutination. Extensive study had failed to reveal crossing in either of these reactions between members of separate groups. The fourth group was formed of a series of independent varieties which could not be definitely related to one another by the immune reactions employed. Up to the present time they had observed no tendency of these organisms to lose their specific characters, nor had they observed a change of one type into another. These groups varied in their pathogenicity for human beings, and in the order of their virulence were as follows: Group III, Group II, Group I, and Group IV. In a series of 103 cases there were 28 cases belonging to Group I of which seven, or 25 per cent., died: of Group II there were 25 cases of which nine died, or 36 per cent.; of Group III, there were 17 cases of which eight died, or 47 per cent.; of Group IV, there were 33 cases of which two, or 6 per cent., died. In view of these constant differential characters of the pneumococcus, it was deemed advisable to study the pneumococcus occurring in normal sputum. It had been commonly assumed that infection in pneumonia was autogenic, and occurred from the invasion of the lungs by a pneumococcus habitually carried in the mouth. If this was so, one should find the same types in the normal mouth as occurred during the disease. Examination of a series of normal individuals showed that this was not the case. In no instance was an organism found which could be grouped with any of the fixed types of pneumococcus. All exhibited the same characters as those organisms obtained from lobar pneumonia which belong to group IV. Inasmuch as organisms belonging to this group were of low virulence, and were responsible in their experience for only 20 per cent. of the cases of pneumonia, it was at once manifest that the majority and more virulent cases of pneumonia were due to organisms which were not found in normal mouths. To gain further evidence of this difference, a study had been made of convalescents from pneumonia who had been infected by typical organisms. During the period of recovery these typical organisms were supplanted by the type which occurred in normal mouths. The period of disappearance of the typical varieties had varied. The shortest time in which disappearance had occurred had been twelve days, and the longest period in which typical organisms had been carried had been ninety days. He had said that the virulent types did not occur in normal mouths. There are exceptions to this observation. In a number of instances organisms belonging to the typical groups had been isolated from the mouth sputum of healthy individuals. A study of the mouth flora of individuals closely associated with twenty cases of pneumonia had shown the presence of a typical disease-producing pneumococcus belonging either to Group I, II, or III in eight instances, or 40 per cent. So far this had occurred only in individuals intimately in contact with cases of lobar pneumonia. Wherever typical organisms had been obtained under such circumstances, the type had always corresponded to that with which the case of pneumonia was infected. Such individuals, therefore, became infected with virulent types of the pneumococcus by contact, and might be regarded as healthy carriers of disease-producing types. This study made it probable that the majority of cases of pneumonia were dependent upon either direct or indirect contact with a previous case. Mere infection of the mouth by virulent types was by no means sufficient to cause the disease. In order to invade the lungs, these virulent types must find the circumstances favorable, or a suitable condition must arise during the period when they were harbored in the mouth.

Varieties of Meningococci.—Dr. SIMON FLEXNER presented this paper in which he stated that two aspects of the specific treatment of epidemic meningitis stood to-day in the foreground. The first related to the question of the varieties of meningococci, the second to the effects of antiseptic agents carried into the cerebrospinal membranes with the antimeningococcic serum. The second question would be dealt with by Dr. Auer. He would confine his remarks to the first. It was originally supposed that all meningococci were alike and constituted a uniform group of microorganisms. As variation among bacterial groups was now quite a common finding, it did not arouse either surprise or misgiving to find that similar variations existed among meningococci. The subject was important, especially as it affected the value of the antimeningococcic serum. The fact was early recognized that certain cases of epidemic meningitis failed to respond to serum treatment. While in the great majority of cases, which did respond, the immediate effect of the serum was to inhibit the multiplication of the meningococci and bring about more active phagocytosis, in the exceptional cases which did not respond the multiplication was unaffected and phagocytosis remained minimal. It was customary to speak of the diplococci in the latter instance as fast to the serum. Dopter was the first to isolate a form of the meningococcus which, while agreeing culturally with the common variety, differed from it in immunological reaction; and this variety to which he gave the name of parameningococcus had now been found in a number of instances in cases of epidemic meningitis. It had been present also in those exceptional cases of meningococcus septicemia without meningitis. The question arose as to whether the parameningococcus occurred also in this country and constituted the serum-fast variety of the meningococcus previously referred to. Having failed to obtain living cultures of Dopter's parameningococcus through the mails, Dr. Louise Pearce of the Rockefeller Institute volunteered to make a quick journey to Paris to secure them. She devised an ingenious method for cultivations on the return journey by employing an electric pad connected with the electric outlet in her stateroom. The two cultures obtained survived the journey. They were studied by Dr. Wollstein and compared with many strains isolated in this country. The two cultures were found to differ considerably from the normal strains of meningococci and, indeed, to differ somewhat from each other. More-

over, two similar and closely corresponding strains were found among the series of cultures employed by the Department of Health of New York City, in immunizing horses for the preparations of the antimeningococcic serum. The properties which distinguish the "para" from the normal strains of meningococci proved not to be absolute but merely differences of degree. But the differences were sufficiently great to account for the lack of power of antisera prepared with normal strains to influence the "para" strains. Hence he recommended the employment for immunization purposes, in the production of antimeningococcic serum, of the "para" strains, which could either be added to the other strains or could be used to immunize particular horses whose serum was mixed with the serum desired from other horses treated with the normal strains. The latter was Dopter's method employed at the Pasteur Institute. Looking toward this end, the Rockefeller Institute had distributed parameningococcus cultures to the several manufacturers of antimeningococcic serum in this country. The war in Europe had brought a considerable demand for antimeningococcic serum which was being supplied in large quantities from this country.

Some of the Effects of Antimeningitis Serum When Injected Intraspinally.—Dr. JOHN AUER made this presentation, which consisted of a series of lantern slides, which illustrated the effect of massive intraspinal doses of antimeningitis serum upon the blood pressure and respiration of monkeys and dogs. The sera employed were antimeningitis serum preserved by 0.3 per cent. tricresol (New York Board of Health), or by 0.3 per cent. chloroform (Massachusetts Board of Health) or normal horse serum preserved by 0.3 per cent. ether. The series of curves demonstrated in general the following points: In monkeys tremendous doses of 0.3 per cent. tricresol serum might be injected intraspinally with only slight effects on the respiration, and with only a transitory lowering of the blood pressure. Thus, for example, a monkey weighing 3,455 grams received intraspinally on one day 5+ c.c. of tricresol antimeningitis serum; on the next day 6 c.c. per kilo, and was in excellent condition at the end of the experiment. Dogs on the other hand were quite sensitive to the intraspinal injection of tricresol serum and both the respiration and blood pressure were markedly affected. Artificial respiration was necessary to keep this species of animal alive when more than about 2 c.c. of tricresol serum per kilo were injected intraspinally. This effect of tricresol serum in the dog was not attributable to a paralysis of the medullary centers, but to a stimulation of the excitatory and inhibitory functions of these centers. For example, after larger doses of 0.3 per cent. tricresol serum, intraspinal injection of this serum might cause a marked slowing of the heart rate (stimulation of the vagus center), a strong rise of the blood pressure in spite of this slowing of the cardiac rate (stimulation of the vasomotor center), and an initial stimulation of the rate and amplitude of the respiration, followed by a stoppage in passive expiration (inhibition of inspiration), this in turn being succeeded by slow respirations with inspiratory pauses (stimulation of inspiration). That the dog's medullary centers were not damaged was also shown by the promptness with which recovery of the normal blood pressure and respiration occurred provided that artificial respiration was maintained for some time. When the blood pressure and respiration both were profoundly affected by the intraspinal injection of 0.3 per cent. tricresol serum, increased cerebrospinal pressure played an important causative rôle. This was demonstrated by showing curves where the mere withdrawal of spinal fluid in a *monkey* whose blood pressure was less than 30 m.m. and whose respiration was feeble and gasping sufficed in a few minutes to restore the blood pressure and respiration to normal. In the *dog* it was shown that the local application of tricresol serum to the medulla (a procedure which practically excluded pressure) did not cause the same effect as its intraspinal injection; by a local application the blood pressure was hardly affected and only very occasionally did the respiration show a transitory stoppage. For these reasons it was recommended that all intraspinal injections in the human subject be given by the gravity method, for this method permitted a slow introduction which reduced the pressure factor and at the same time a quantity of the injected fluid could readily be withdrawn should a reduction or failure of the respiration or blood pressure demand this. In addition it seemed advisable to be prepared to administer efficient artificial respiration if necessary; Meltzer's pharyngeal insufflation apparatus might be recommended for this purpose. The gravity method, however, was no guarantee against raising the intraspinal pressure, for the pressure in the gravity system must be greater than the intraspinal pressure or otherwise no serum would enter, unless the absorption of the injected serum was as rapid as its inflow, a condition which probably did not occur in practice. Serum preserved by 0.3 per cent. chloroform or ether produced in general a less marked effect on the blood pressure and respiration of dogs than 0.3 per cent. tricresol. Nevertheless, dangerous alterations of these functions were also observed in the dog, but not in the monkey, with these preservatives (which were not removed before injection) as well as with normal sera containing no preservatives at all. The best preservative for therapeutic sera was theoretically a volatile one which could be driven off by warming the serum container before the serum was incorporated. Ether was better in this respect than chloroform. Finally, it must be emphatically pointed out that antimeningitis serum was the only remedy they possessed against epidemic cerebrospinal meningitis and that its rational employment had changed the former mortality of about 70 per cent. to less than 30 per cent. With the aid of antimeningitis serum the patient had not only 70 chances out of a 100 for recovery, where he formerly had only 30, but he had also the additional advantage that the use of the serum markedly reduced the frequency and severity of those distressing sequelæ which characterized epidemic cerebrospinal meningitis.

Studies on the Therapeutic Action of Digitalis.—Dr. ALFRED E. COHN read this paper, in which he said that the administration of digitalis to patients had been difficult because there had been no specific criterion telling when the drug was effective. In the course of other studies it was found that a change in the electrocardiogram occurred, which could be used for the purpose indicated. It consisted in an alteration, sometimes an inversion, of the *T* wave. The change might occur as early as twenty-four hours after the administration had commenced. It might persist as long as twenty-two days after the use of the drug had been discontinued. The electrocardiogram had been seen to return to normal after five days. By the use of this sign, two actions on the heart were detected, when digitalis was given. The rhythm of the heart might be changed and the *T* wave of the electrocardiogram was altered. If atropine, which acted on the vagus terminals, was injected, the rhythm of the heart was restored to normal, but the change in the *T* wave persisted. The alteration in rhythm indicated an effect of digitalis on the nervous system; the alteration in the *T* wave, an effect on the heart muscle. There was, therefore, evidence to show that the action of digitalis on the heart was twofold, nervous and muscular.

Dr. A. JACOBI asked Dr. Cohn how long were the intervals between the doses he gave.

Dr. COHN replied that the dose given was equivalent to 0.1 gram of the powdered leaves of digitalis given four times a day. The following day he gave the same dose, so that the patient under discussion received 0.4 grams each day. This amount was given for three days and then 0.3 was given on the fourth day.

Dr. A. JACOBI said that he wished to learn what practical results had been obtained from such experiments as Dr. Cohn had carried out and what practical value they had for the general practitioner. Practitioners wished to apply what the experimenters taught them. Dr. Jacobi said that what Dr. Cohn had stated reminded him of what he had seen in his practice and particularly with the doses of digitalis he had given, sometimes small and sometimes large. He considered that the dose of digitalis Dr. Cohn had given was a sufficiently large dose if continued long enough. Smaller doses of this drug were demanded for certain purposes. The question whether digitalis was a nerve or a muscle remedy had been decided some time ago. When digitalis produced early vomiting, this should be considered the result of nerve influence. At the same time, they all knew that it acted as a muscle stimulus. He recalled a desperate case of meningitis in the President's service occurring in a child of 13 years; this patient had a high temperature and a pulse of 150 to 160. He suggested that digitalis be given and was asked how much at a dose. He said that the patient should be given one drachm of the good tincture of digitalis as a first dose. This was given and the patient did not die the same day, but about three weeks

afterward. The dose was repeated in one-half this amount several times that day. Such doses he had frequently given and had preached about. In adults with pneumonia, when on the second or third day there was beginning edema of the lungs with cyanosis and where in a number of cases only large venesections would give results, he had given 10 grains of digitalis and in one dose. He had found that such cases of pneumonia would not get well unless 10 minims of the fluid extract of digitalis was administered with, or at the time of, a venesection. Such cases required within three or four hours another dose of digitalis, and sometimes a third dose, three, four, or five hours afterward. A number of such cases might get well with this treatment subcutaneously or internally which would not recover under other treatment. Dr. Jacobi said that when he wanted to give digitalis when he was dealing with a weak heart in tuberculosis, chlorosis, etc., he gave it for a long time, three or four months or more, but he could not give the dose Dr. Cohn gave. He could give three, or at most, five grains a day, day after day, and he never had any cumulative effects and no arrhythmia. What he had just offered was the result of practical experience and he thought that possibly it might be a guide to those gentlemen who were experimenting with digitalis.

The Rôle of Lymphocytes in Experimental Tuberculosis in Mice.—Dr. James B. Murphy presented this communication. He stated that the fact that in the reaction to tuberculosis infection the part played by the endothelioid cell or endothelial leucocyte had received so much attention in recent years was probably due to the early appearance of these cells in the process of formation of the tubercle and because of their well known phagocytic activities. The lymphoid cell, probably because of its later appearance and its lack of phagocytic power, had been almost neglected. Observers, however, had noted that in rapidly fatal miliary tuberculosis the lymphocytes fell often to below 10 per cent. of the circulating white cells, whereas in patients with early healed or healing tuberculous lesions these cells were increased, sometimes forming more than 50 per cent. of the total leucocytes. Moreover, it was well known that while in acute rapidly fatal miliary tuberculosis relatively few lymphocytes occurred in the tubercles, in the subacute form, where a higher resistance of the individual might be assumed, the tubercles contained large numbers of lymphoid cells. These facts had a close analogy in the reaction of the polynuclear leucocytes in certain infections against which they were presumed to form the chief resisting factor. Until recently the round-celled infiltration occurring about slowly growing or healing cancer, about cancer grafts in immunized animals, and about failing tissue grafts, had been assigned, as in tuberculosis, a secondary rôle. The lymphoid elements in both instances were supposed to be present as the result of tissue disintegration. Recently it had been shown that in the case of tissue grafts, the lymphocytes in all probability were the chief agents in causing destruction of the introduced tissue. Hence, it seemed probable that the lymphoid cell might play a more important rôle in the resistance to certain infections than had hitherto been supposed. In differential counts made on the blood of mice before and at intervals after splenectomy they found that 80 per cent. of the animals showed a marked reduction in the circulating lymphocytes during the first week, while those counted 19 to 21 days after splenectomy, 75 per cent., showed an average increase of over 11,000 lymphocytes per c.mm., a gain of more than 100 per cent. The remaining 25 per cent. which had not gained showed a count slightly below normal, averaging a loss of less than 8 per cent. In experimenting with reference to the effect of the *x*-ray on lymphoid tissue they had found that by carefully regulated doses of *x*-ray, repeated at intervals, a gradual atrophy of the lymphoid tissue might be accomplished without any appreciable effect on the other tissues, or the general health of the animal. In a series of experiments planned with the idea of testing the resistance of animals to tuberculosis when the amount of lymphoid tissue was varied, the *x*-rayed animals, having a system greatly depleted, should be the first to die of the disease. Next came those splenectomized shortly after the inoculation, and they might be considered as having a reduced amount of lymphoid tissue. The animals inoculated eight to ten days after splenectomy, with an active proliferation of the lymphoid cells in the glands and elsewhere at this stage, should be more resistant than the above. Among the animals, however, splenectomized three or more weeks before inoculation, a certain per cent. should outlive the normals. Dr. Murphy exhibited charts showing the death rate of the various groups after inoculation with the tubercle bacillus. Animals splenectomized and given a series of treatments with the *x*-ray and animals simply given the same dosage of *x*-ray survived on an average of about seven days after inoculation. The animals splenectomized a short time before inoculation survived on an average about nine days. The animals splenectomized ten days before inoculation survived on an average 19 days, which was one day longer than the normal animals. Animals splenectomized 3½ weeks previous to inoculation survived about 26 days, but some of the animals in this group lived considerably longer than any of the animals in the other groups. The question naturally arose whether these treatments caused variations in factors other than the lymphocyte which might play a part in the resistance to tuberculosis. The author considered the other factors that might enter into the problem and showed that they might be excluded. The well known association of the lymphocytes with tuberculous lesions tended to support the conclusion indicated by the experiments. It seemed, therefore, that the known facts in reference to the lymphocytes in tuberculosis taken in conjunction with these experiments suggested that the lymphocytes played an important rôle in the animals' resistance to tuberculosis.

Dr. Max Einhorn said that in 1884 he had made a study of the relation of the lymphocytes to the other white blood corpuscles and he found at that time that the lymphocytes in a normal individual amounted to 25 per cent., that was, the relation. In disease he found there was a great variation. In his dissertation he pointed out that the mononuclears were much diminished while the polymorphonuclears were much increased. In that paper he told of following up cases of septicemia where he had made a study of the relation of lymphocytes and the polymorphonuclears every day until the death of the patient. There was an increase in the polymorphonuclears and a decrease in the mononuclear elements. He pointed out at that time that this was of great prognostic importance. The mononuclears played an important part in the protection of the body. His paper was originally printed in German in 1884 and later on was translated and published in the *Post-Graduate*, 1906.

Philadelphia Pediatric Society.

At a stated meeting held February 9 Dr. Simon Flexner, of the Rockefeller Institute, delivered an address entitled "Etiology and Mode of Infection of Epidemic Poliomyelitis." He pointed out that the disease had been epidemic continuously on a large scale in the United States since 1907, although occasionally small epidemics had been recorded at other times, as for example one in Vermont in 1894. The most intensive studies of the disease in recent times had been made by Wickman, a Swedish observer. He it was who from the statistical standpoint, was the first to record the occurrence of so-called abortive cases in which there occurred fever and malaise, perhaps with slight transitory muscular weakness, but without permanent paralysis. Since that time the disease has been conclusively demonstrated to be dependent upon the activity of a filterable virus, which only within the most recent times has been cultivated upon artificial media and distinguished in stained preparatons with high powers of the microscope. That the disease is due to a specific cause has been shown by causing its development in monkeys by inoculating them with emulsions of nervous tissue from fatal cases of the disease. From animals thus infected the disease could be consecutively conveyed to other animals similarly inoculated. One attack of the disease appears to confer immunity to subsequent attack, and this fact was utilized in establishing the identity of the so-called abortive cases. It was found that when blood-serum of an individual who has had the disease, even many years previously, is added to active virus, no symptoms develop when the mixture is introduced into experimental animals, as had previously been demonstrated for classic types of the disease. Examination of cerebro-spinal fluid obtained by lumbar puncture affords a valuable means of diagnosis in the abortive cases and in the preparalytic stage of ordinary cases, an increased number of lymphocytes and an increased globulin-content being present under such

conditions. Recently, by inoculation of diseased tissue upon sterile, not sterilized, ascitic fluid, it has been possible, not without difficulty, to obtain a growth, under anaerobic conditions, and by means of staining with Giemsa's methylene blue, to recognize a minute globular body as the probable etiological factor. Then by inoculations of this growth the disease can be reproduced in monkeys and from the nervous tissues of these experimental animals the micro-organisms can in turn be recovered. The germ has been found in the central nervous system, the brain and the spinal cord, in the Gasserian ganglion, the intervertebral ganglia, the abdominal sympathetic ganglia, the secretions and tissues of the upper respiratory tract, especially of the nares, the contents and tissue of the gastrointestinal tract and the mesenteric lymph-nodes, but never in the blood or other viscera. The disease can be induced in lower animals most readily by direct introduction into the cerebrospinal fluid, or the nerve tissues, and with almost equal facility by introduction into the nasal passages. Accordingly, there is good reason for believing that this is the channel through which infection commonly takes place in human beings, although it has been shown in one set of experiments that a biting insect, the stable-fly, *Stomoxys calcitrans*, played the part of an intermediary agent. While, thus, the disease is usually transmitted from those suffering therefrom, it is sometimes, like other diseases, for example typhoid fever and diphtheria, conveyed through individuals who harbor the specific germ, but do not themselves present symptoms of the disease, namely carriers. These constitute an especial source of danger because they are likely to escape recognition, and the necessary prophylactic measures will accordingly not be instituted. Further, no distinction can be made, clinically, bacteriologically, or pathologically, between sporadic and epidemic cases of the disease.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

June, 1914.

(*Concluded from page* 546.)

OBSTETRICS.

1. What degree of pelvic contraction is compatible with delivery.
2. How do you measure the conjugate diameters?
3. How should uterine inertia be treated?
4. What is the treatment of placenta prævia when occurring before the full term?
5. What are the dangers in a breech presentation.
6. When should the forceps be applied and what preliminaries are necessary in their application?
7. What alternatives do we possess to the use of the forceps?
8. Describe the ligaments of the uterus.
9. Describe the operation of transfusion.
10. Give the treatment of caruncle.

SURGERY

1. Give the differential diagnosis between acute catarrheal conjunctivitis and gonorrheal ophthalmia, and the general principles of management of each.
2. Name the varieties of goitre and mention the indications for surgical interference.
3. Describe the fractures commonly designated as: (*a*) Colles' fracture. (*b*) Pott's fracture. Give treatment of each.
4. Give the differential diagnosis between a fracture of surgical neck of humerus and a dislocation of the shoulder joint.
5. Give diagnosis and treatment of epithelioma of the lower lip.
6. Name the varieties of tumor of the bladder, with symptoms of each.
7. Give the differential diagnosis between appendicitis, cholelithiasis and ulcer of the pylorus.
8. Give the symptoms, diagnosis and treatment of tuberculous disease of the hip joint.
9. Name the varieties of fistula-in-ano and give the treatment for same.
10. Give symptoms and treatment of acute osteomyelitis.

ANSWERS.

OBSTETRICS.

1. The following table (from King) is a safe guide:

When Conjugate Diameter of Brim measures:	The Mode of Delivery at Term is:
Between 4 and 3½ inches.	By Forceps.
Between 3½ and 2¾ inches	By Forceps, Version. Symphyseotomy. Cesarean section, or Craniotomy, *pro re nata*.
Between 2¾ and 2 inches.	Cesarean section, if child alive. Craniotomy, if child dead.
At 2 inches or less.....	Cesarean section always. Craniotomy excluded, whether child dead or alive.

2. "The *conjugata vera*, or true conjugata, is measured from the center of the promontory of the sacrum to that point on the posterior surface of the upper end of the symphysis pubis which is crossed by the iliopectineal line. This is the shortest diameter at the brim through which the head must pass. It cannot be accurately measured, but is estimated in the normal pelvis at 10.5 to 11 centimeters (4¼ to 4½ inches). The *diagonal conjugate* is measured from the summit of the subpubic arch, or the subpubic ligament, to the promontory of the sacrum; it is from this diameter that we estimate the true conjugate. To estimate the true conjugate from the diagonal, we deduct from ½ to ¾ of an inch (1.5 to 2 centimeters). The amount to be deducted depends (*a*) on the depth of the symphysis pubis—the greater the depth the greater must be the allowance; (*b*) on the thickness of the pubic symphysis, for increase in the thickness increases the allowance to be subtracted; (*c*) on the inclination of the symphysis and the inclination of the brim of the pelvis, for when the promontory is high a greater deduction must be made." (Polak's *Manual of Obstetrics*.)

3. "*Treatment of uterine inertia:* Endeavor to ascertain and remove the cause. Place the woman under the best hygienic conditions. If the source of reflex disturbances cannot be removed, we may quiet the nerve center by chloral, opium, or the bromide of potassium, after which the inertia is commonly relieved. When the patient is suffering from fatigue during a protracted labor, quinine is of great use. Massage and stroking of the uterus through the abdominal walls may be tried. If over-distention exists we should early rupture the membranes." (Landis' *Obstetrics*.)

4. "PLACENTA PRÆVIA. *Treatment before term:* Rest in bed, with or without a *tampon*, will arrest hemorrhage for the time; the sinuses are closed by thrombi, and the case may go on to term or another hemorrhage. The patient should be allowed cold drinks; opium may be used where pain is present. If the hemorrhage is great, it is safer to induce labor at once than to wait. Occasionally no hemorrhage occurs during pregnancy, not even in labor." (Landis' *Obstetrics*.)

5. The danger to mother and child in a case of breech presentation are: (1) Compression on the umbilical cord; (2) premature respiration; (3) asphyxiation of the child; (4) the child may suffer from fractures, dislocation, hemorrhage, or paralysis; (5) extension of the head, or of the arms over the head; (6) increased tendency to rupture of the perineum.

6. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (a) Impending exhaustion; (*b*) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior, (*b*) mento-anterior face, (c) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapsed funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both (Jewett). *Conditions necessary for the use of forceps* are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

7. *Alternatives to the use of forceps*, are: Version; induction of premature labor; craniotomy, or some other mutilating operation on child; cesarean section or one of its modifications; symphyseotomy; pubiotomy.

8. The LIGAMENTS OF THE UTERUS are: (1) *Broad ligaments*, which extend outward on each side from the side of the uterus to the side of pelvis. (2) *Rectouterine ligaments*, which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments*, which extend from the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) The *ovarian ligaments*, which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) The *uterosacral ligaments*, which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac synchondrosis.

9. "*Transfusion* is the transmission of blood from an artery of one person to the vein or artery of another. It requires careful technique, involves the willingness of a second person to contribute blood, and is not free from danger. The dangers are: (1) Clotting; (2) the transmission of disease, such as syphilis; (3) the collapse of the donor of the blood, and (4) hemolysis. Before transfusion the blood of the donor should be tested with that of the patient for fear of hemolysis. This is especially likely to occur in infants or in the presence of a malignant tumor (Crile). By recent improved methods the clotting and technical difficulties have been much reduced, so that transfusion, which was at one time abandoned, has again come into general use. The artery of the donor is usually connected with a vein of the recipient by some apparatus, and the blood allowed to flow gently for fifteen or twenty minutes, or until the donor begins to show the effects of loss of blood. In some cases transfusion into an artery brings a more prompt response than into a vein. For in transfusion into a vein the transfused blood may merely increase the volume of the already excessive venous blood, and in any case must pass to the right heart and through the pulmonary circulation before the left heart can act upon it; while by transfusion into an artery the new blood, owing to the increased peripheral resistance, stimulates the heart and invigorates the coronary circulation." (Bastedo's *Materia Medica.*)

10. *Treatment of caruncle:* It should be excised or destroyed with the electric cautery.

SURGERY.

1. "ACUTE CATARRHAL CONJUNCTIVITIS. *Symptoms:* Hyperemia, profuse lacrymation, epiphora, a profuse discharge, sensation of sand in the eye, and sometimes photophobia. *Treatment:* Astringent and antiseptic washes are of value. Ascertain the underlying cause, if possible, and remove it. Anointing the lids with pure or medicated vaseline every evening is necessary. Alum, tannic acid, silver nitrate, and zinc sulphate are valuable as astringents. In intractable cases a 50 per cent. solution of boroglycerid in glycerin should be applied once daily."—(*Cyclopedia of Practical Medicine and Surgery.*)

2. GONORRHEAL OPHTHALMIA. *Symptoms:* Swelling and redness of the eyes, the presence of a discharge which soon becomes purulent, the conjunctiva of the lids becomes thickened, the eyelids are edematous, pain is severe, and there is some fever. *Dangers:* Ulceration and sloughing of the cornea, perforation of the anterior chamber, and blindness. *Management:* Protect the sound eye. Wash the eye carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped onto the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt. In adults the irrigation must be frequent, about every half hour or hour.

2. *Parenchymatous goiter:* "Operative treatment is indicated when there are symptoms referable to pressure on the air-passages, esophagus, or blood-vessels, especially if there are signs of commencing cardiac disturbance; and in goiters which are steadily increasing in size. The evidence of a goiter becoming malignant is also a reason for removing it by operation. Kocher considers it advisable to operate if the patient becomes breathless by making pressure on the goiter from side to side."

Adenomatous goiter: "The only treatment is to enucleate the adenomata or cysts from the gland. The thyroid is exposed by a transverse curved incision, the tissue covering the nodule is incised, and the adenoma shelled out."

Malignant goiter: "It is only in the earliest stages that a malignant goiter can be successfully removed. In the later stages complete extirpation is not to be attempted, as it usually involves the removal of a portion of the trachea or esophagus, and the operation generally proves fatal. Operative interference is often called for, however, for the relief of respiratory embarrassment. Tracheotomy may prove a very difficult and dangerous procedure, owing to the trachea being buried under the goiter and displaced or narrowed by it, so that it is not easy to reach the trachea or to introduce an efficient tube beyond the point of obstruction. A more certain method consists in exposing the goiter by an incision as for thyroidectomy, rapidly removing sufficient of the growth to expose the trachea and admit of a tube being introduced. If there is a retrosternal prolongation compressing the trachea within the thorax, a long flexible lead tube may have to be passed beyond the site of the compression before the dyspnea is relieved."

Exophthalmic goiter: "Excision of one lobe of the thyroid together with the isthmus and the pyramidal lobe is indicated in all cases that do not present degeneration of the heart muscle, with irregular pulse and low blood pressure. The superior thyroid artery of the opposite side may be ligated with advantage." (Thomson and Miles' *Manual of Surgery.*)

3. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backwards and upwards, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking-hands" grip, extending and adducing the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later than the end of the first week, to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery.*)

Pott's fracture is very common, and is due to indirect violence, such as turning over on the inside of the foot. The strain tears through the internal lateral ligament of the ankle or tears off the tip of the malleolus; then the astragalus is pressed against the inner side of the external malleolus by the continuation of the violence. The fibula is overbent, and breaks about 3 inches above the tip of the malleolus. At the same time the foot is displaced outwards or outwards and backwards. *Treatment:* An anesthetic should always be given, and the fracture reduced by relaxing the calf muscles and applying traction to the foot. The limb must then be fixed on a back-splint, with side-splints in addition. The foot must be at right angles to the leg, the bony points in line, and the posterior displacement corrected. The surest way of maintaining the foot in good position is to at once apply plaster of Paris. Other splints used are Dupuytren's and Syme's horseshoe splint. Massage and passive movement at the end of ten days are advisable, the fragments being firmly grasped to prevent displacement.—(*Aids to Surgery.*)

4. In *fracture of the surgical neck of the humerus*, the head of the humerus will be found in the glenoid cavity, but it will not rotate with the shaft; the arm will appear shorter; and crepitus and abnormal mobility will be elicited unless there is impaction.

In *dislocation of the shoulder joint*, the glenoid cavity will be empty, and the head of the bone will be found in an abnormal position; the arm will appear longer; there will be no crepitus, and no abnormal mobility.

5. *Epithelioma of the lower lip.* "The ulceration spreads along the lip, chiefly towards the angle of the mouth, and downwards towards the chin, and the sub-

stance of the lip becomes swollen and indurated. The edges are characteristically raised and hard, and the raw surface is extremely painful, especially when irritated by hot food or fluids. The growth is liable to spread to the mucous membrane and gum, and to invade the lower jaw. The disease spreads early to the submental and submaxillary glands, which are best felt with one finger inside the mouth, under the tongue, and another outside below the jaw. The infected glands tend to become fixed to the jaw, and to soften, liquefy, and fungate. Metastasis to internal organs is rare. Unless removed by operation, the disease usually proves fatal in from three to three and a half years. The *treatment* consists in early and free removal of the affected portion of the lip and of the infected glands. In comparatively small growths which do not involve the angle of the mouth, a V-shaped incision is carried through the entire thickness of the lip so as to include the disease and an area of healthy tissue beyond it. In larger growths, particularly when situated at the angle of the mouth, it is necessary to carry an incision transversely into the cheek to enable the lip to be repaired without leaving deformity. When it is necessary to remove the greater part of the lower lip, the defect may be filled up by flaps of skin taken from below the jaw (Syme's operation). When the tumor is adherent to the lower jaw, it is necessary to resect a portion of that bone along with the lip. The frequency with which recurrence takes place in the lymphatic glands below the jaw renders it advisable to remove these in all cases, whether they are palpably enlarged or not. J. Hutchinson, Jr., recommends that the submaxillary and submental triangles on both sides should be cleared out as a routine procedure."—(Thomson and Miles' *Manual of Surgery.*)

6. Tumors of the bladder are benign, and malignant.

Benign tumors. "The only *symptom* in the early stage is hematuria, which lasts from a few hours to weeks. After an interval the bleeding recurs. No other symptoms occur till later, when pain and frequency of micturition, due to cystitis, make their appearance, while interference with the outflow may arise from blockage of the neck of the bladder by the growth. Portions of the tumor may be passed. On rectal examination or with the sound, nothing abnormal can be felt. With the cystoscope the tumors may be distinctly seen. If the ureteral orifice is affected, pain may occur early and be referred to the loin. Recurrence after removal is common."

Malignant tumors.—Symptoms.—"Hemorrhage appears later than in simple tumors, but is more persistent. Pain is a constant early symptom, accompanied by frequency of micturition, chiefly due to the quick onset of cystitis. In the harder forms of growth irritability of the bladder precedes the hematuria. Shreds of growth may be found in the urine. Interference with the flow of the urine is caused by involvement of the neck of the bladder, hydronephrosis by affection of the orifices of the ureters. With a sound, a tumor may be felt projecting into the bladder; *per rectum* a hard mass may be felt in the base of the bladder; while with the cystoscope the ulcerated surface may be seen. The vesical wall may become perforated, causing extravasation, cellulitis, or a recto-vesical fistula. Death occurs from exhaustion or spread of sepsis to the kidneys." (*Pocket Cyclopedia of Medicine and Surgery.*)

7. In *appendicitis*, there is pain of a severe type, colicky in character, and of sudden onset; nausea and vomiting; and localized tenderness and muscular rigidity in the right iliac region.

For *cholelithiasis*, see above, PRACTICE, question 6.

In *ulcer of the pylorus*, the pain is in the epigastric region, may radiate to the left shoulder, and is increased by taking food (usually about one to three hours after a meal); vomiting may occur from one to four hours after eating; hemorrhage may be present; the acidity of the gastric content is above normal, owing to excess of free hydrochloric acid.

8. TUBERCULOUS DISEASE OF THE HIP. "There are three stages of the disease: (1) That which extends from the beginning to the development of pus in the joint, and is characterized by localization of the disease, flexion, limping, pain, usually referred to the knee, slight induration about the joint, fixation and atrophy of the muscles, and enlargement of the neighboring glands. (2) The stage that extends from the end of the first stage until the development of pus outside of the joint, or the stage of joint involvement, and is characterized by abduction and apparent elongation, night cries, abscesses, joint crepitation, and failure of the general health, in addition to the symptoms of the first stage intensified. (3) The stage that extends from the end of the second stage to the termination of the disease or the stage of destruction of the capsule and external suppuration. Adduction, flexion and real shortening are present, and dislocation and ankylosis or suppuration, destruction of the joint, asthenic symptoms, and death result.

"The *cardinal symptoms* of the hip-joint disease are the spasm, wasting, lameness, deformity (real and apparent), pain, and swelling. Careful attention to these will make the diagnosis easy. The tendency of the disease is toward recovery, but the prognosis is greatly influenced by the age, type of disease, complications, and treatment. Death usually occurs from amyloid changes in the viscera.

"*Constitutional treatment* consists of improved hygiene, good food, fresh air, and the administration of tonics, such as iron and the hypophosphites, and alteratives, such as cod-liver oil, iodine, and its salts. A change of climate is sometimes beneficial. Locally, iodine, blisters, hot water bottles, or hot water dressing may be applied.

"The *special treatments* consist of the mechanical treatment, treatment of the complications, and the surgical treatment. The mechanical treatment consists of recumbency for two or three weeks in uncomplicated cases, with fixation and traction. Continuous traction may be first obtained by Buck's or Sayre's extension apparatus, made of adhesive plaster, later by means of a traction splint, with crutches, and still later by the traction splint alone, a high shoe being worn on the sound side, which in a year or two may be discarded. A modified traction splint may be made of plaster of Paris. Differences of opinion exist as to when the abscesses should be incised, but always the strictest asepsis or antisepsis is necessary. Irrigation of the cavities with sterile water, boric acid solution, or mercuric chloride solution, 1:4000, and the injection of sterile iodoform oil, 5 to 10 per cent., are commonly resorted to. Osteotomy and fixation may be required for the deformity arising as a complication. The surgical treatment consists of aspiration, incision, erasion, and excision."—(*Pocket Cyclopedia of Medicine and Surgery.*)

9. FISTULA IN ANO.—*Varieties.* 1. Complete.—Sinus opens into the rectum internally; on to the perineum externally. 2. Incomplete external—A perineal sinus not opening into the rectum. 3. Incomplete internal—A sinus opening into the rectum, but not externally.

Treatment. Preliminary.—Saline aperients for several days. Opium pill, gr. j. twelve hours before. Enema just before operation. *Operation.*—Pass a director up the fistula. Open it completely from end to end. Scrape out all granulations and cut out scar tissue. Cut through all tissue between rectum and the fistula, including the sphincter ani. Open up all secondary channels and sinuses. Pack deeply with oiled gauze. In cases in which the fistula is superficial to the sphincter, the latter should also be deeply incised as in the case of a fissure. *In chronic or complicated cases.*—Either excise in the lower end of the rectum, retaining the sphincter (Kraske's operation); or perform an inguinal colotomy."—(Grove's *Synopsis of Surgery.*)

10. ACUTE OSTEOMYELITIS. *Symptoms:* Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia, may be present.

Treatment consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION.†
Alabama*	W. H. Sanders, Montgomery	Montgomery...July 13
Arizona*	J. W. Thomas, Phoenix	Phoenix
Arkansas	W. S. Stewart, Pine Bluff	Little Rock...May 11
California	C. B. Pinkham, Sacramento	San Francisco .April 13
Colorado	David A. Strickler, Empire Building, Denver	Denver
Connecticut*	Chas. A. Tuttle, New Haven	New Haven...July 13
Delaware	J. H. Wilson, Dover	Dover...June 15

Therapeutic Hints.

Treatment of Motorists' Conjunctivitis.—G. S. Ryerson recommends the following:

℞ Solution of suprarenal extract (1-1000), ♏xx.
Boric acid, gr. v.
Sodium biborat, gr. x.
Peppermint water, ♏xx.
Distilled water, ad ℥j.

M. Sig.: Instil four or five drops into the eyes three times daily.—*Canadian Practitioner.*

Toothache Drops.—C. A. Ewald and A. Heffter cite the following formula:

℞ Oil of cajuput.
Oil of cloves, āā 1 gram.
Chloroform, 2 grams.

M. Sig.: One or two drops to be applied on a little cotton in the hollow tooth, and a few drops to be rubbed upon the cheek on the painful side.—"Handbuch der Arzneiverordnungslehre."

The Subcutaneous Administration of Quinine.—E. Müller notes that the addition of urethane or antipyrine to a solution of quinine hydrochloride makes the latter suitable for hypodermic administration. The formulæ are as follows:

℞ Quinine hydrochloride, 1 gram.
Urethane, 0.5 gram.
Distilled water, ad 10 c.c.

M. Sig.: For hypodermic injection, 1 c.c. containing 0.1 gram of quinine.

℞ Quinine hydrochloride, 2 grams.
Antipyrine, 2 grams.
Distilled water, ad 10 c.c.

M. Sig.: For hypodermic injection, 1 c.c. containing 0.2 gram of quinine.

—"Die Therapie des praktischen Arztes."

A Lotion for Urticaria.—Coughlin finds that the itching may be greatly relieved with the use of the following lotion:

℞ Phenol, 1.5 gram.
Glycerine, 30 grams.
Hot water, 120 grams.

—*Interstate Medical Journal.*

The Treatment of Flatulent Colic in Infants.—Leonard Williams accredits the following prescription to Widerhofer:

℞ Tincture of cascarilla. ♏x.
Tincture of krameria, ♏x.
Oil of anthemis, ♏j-ij.
Simple syrup, ℥ijss.
Water, ad ℥ij.

M. Sig.: One teaspoonful every two hours.

—"Minor Maladies."

A Laxative Powder.—Leube is said to recommend the following:

℞ Powdered rhubarb, 30 grams.
Desiccated sodium sulphate, 15 grams.
Sodium bicarbonate, 5 grams.
Oil of peppermint, 10 drops.

M. Sig.: One teaspoonful in a tumberful of water at night.

—*Paris Médical.*

Therapeutic Uses of Calcium Chloride.—Savill states that this drug is useful in the treatment of pruritus from any cause, as well as in the treatment of hemorrhage. A palatable solution is the following:

℞ Calcium chloride, gr. xx.
Tincture of orange, ℥ij.
Chloroform water, ad ℥j.

M. Sig.: To be given three times a day.

—"A System of Clinical Medicine."

307, SHERBOURNE ST
TORONTO.

THE ADVANTAGES OF MEDICAL ASSOCIATIONS.*

BY EDWARD C. REGISTER, M.D.,

CHARLOTTE, N. C.

GENTLEMEN of the Tri-State Medical Association:—You will allow me, I am sure, to say how happy was the choice that brings us together in this good city of Charleston. Here perhaps more than any other place in America one feels the fineness and charm of all that made the Old South illustrious in song and story, and also the quickening pulse and hope of the South that is to be. Surely Charleston wears the glory of both yesterday and to-morrow. We count ourselves happy to be within her gates, here where the chivalry of the South, in two historic wars, illumined the annals of our race; here where this city, the virgin daughter of our civilization, is still unfallen, having refused to bow down before the altars of the golden gods; here where the mellifluent voice of the sea, the grave sweet bells of St. Michaels, and the song of quickening industry unite in a harmony that charms our souls.

The eminent physicians and surgeons who through your trust and courtesy, through your personal preference and beneficence, have been permitted to occupy this position, have referred to its honor, to its responsibility, to its obligations, and most feelingly and appropriately to those who have preceded them. When I recall these beautiful references, when I think of the brilliant men who have preceded me as presidents of this association, I feel very deeply my inability to serve you as acceptably as they. Only with your sympathetic support and kindly advice can I hope to sustain the high traditions of this office. I am reassured by the knowledge that I have in you, as co-workers, the sustaining help of no insignificant body of men. After attending these meetings with almost perfect regularity since the Association was organized, I have often remarked that the papers read at your meetings and the discussions are equal, from a scientific standpoint, to those of any medical organization in the United States. The members, as a rule, are thoroughly familiar with the medical and surgical advancements of the day and the many facts and theories that are appearing with such rapidity in every department of our science. By these things I am led to hope that the day is not far distant when we will occupy a larger place among the creative and contributing scholars of our science, when our dependence upon the medical invesigators of other sections and other nations shall be greatly decreased, when out of our travail shall be born men worthy to lead the advancing hosts of medicine and surgery into the light of a more perfect day.

I have chosen to speak to you, gentlemen, upon "The Advantages of Medical Associations." And first I speak of that advantage for which I shall be compelled to coin a term, there being none in use which sufficiently defines my meaning. With your permission I shall call it the process of intellectual confluence. By this phrase I intend to convey an idea of that system of transportation in the kingdom of mind by which the ideas, discoveries and experience of the isolated and individual seeker after truth find their way into the thought and usage of our whole profession. This process is, of course, not confined to us alone. On examination of the journals of the learned scientific societies of Europe, one will see how large a place the process to which I refer has among the greatest scholars and savants of the world; and in proportion as our science is more vital to the physical weal of man, in that proportion should we feel a greater sense of consecration to the most approved scientific processes. An illustration will perhaps make most clear the meaning that I intend to convey by the term intellectual confluence. A raindrop, driven by the wind, falls in the mountain forest. Apparently it is lost, lost to the thirsty field, lost to the power of the waterfall, lost to the lordly river. But observe. The wisdom of the great and mysterious All-Mind has made a sure path by which that drop of rain finds its way at last into the river's fullness, to add to its power to quench the thirst of fruitful fields, and to bear the commerce of the world upon the broad bosom of confluent waters, such as the Ashley and Cooper rivers, upon whose historic banks we are met. There is need for a like process in the world of mind.

Into the mind of a physician who rides on his errand of mercy in his isolated and sometimes lonely country side, perhaps through that same mountain and silent forest an idea falls, an experience comes, and possibly a valuable discovery is made. How will that discovery become the valuable property of our whole profession? Shall it die with its discoverer, and let some fever still burn away the vital power of weary thousands until some other man shall stumble upon it? Clearly there should be an intellectual stream-path by which the truth or discovery can find its way to the universal medical mind. This is precisely one of the most vital functions of the wisely wrought chain of medical associations, by whose intricate and far-reaching ramifications, like the confluent rivers, such individual discoveries may be drained into the records of the central association. The physician of the mountain forest discusses his new treatment with a little group of local associates, and they in a larger

*President's Annual Address. Read before Tri-State Medical Association of the Carolinas and Virginia. Charleston, S. C., February 17, 1915.

group, until by a sure process, through state, tri-state and national associations, their ideas, if valuable, come at last to be the property of our entire medical profession. This particular advantage of the medical associations merits our deep consideration. We cannot overstress this function, this process of intellectual confluence, that drains into our intellectual profession all the valuable medical facts and investigations from all the individual workers in the world. It gives one very genuine sorrow to think how much has been lost through the long ages of the life of medical men upon this planet, because so many facts, truths, ideas, processes and discoveries have died with their discoverer. One cannot stand, as it has been my good privilege to do, among the bleak and sandswept ruins of the civilization of the Egyptians, without being touched by a knowledge that many of those things that made Egypt great have been lost, and some of them even yet undiscovered. And when we think by what a narrow margin of seeming accident most of our boasted medical science has been stumbled upon, our minds are filled with a sense of urgency to do everything to save, perpetuate and safeguard as a golden treasure all those sometimes seemingly small contributions of experiment and experience that go to make the glory of our science. If we had the records we could count thousands of valuable discoveries in our science which have died with their discoverer for lack of a system of intellectual drainage and confluence by which these things might have been taken up and perpetuated for the good of mankind. I know of no better illustration of this process of confluent thought than the circumstances attending the famous discovery of Tischendorf. This eminent German scholar came at night to the door of a monastery on the lonely and tradition-crowned summit of Mt. Sinai. He was admitted by the hospitable monks, and slept in the holy stillness of that mountain cloister. While sitting in the library, he noticed in a waste basket a fragment bearing the Greek words "kata Matthion." To his keen scholar's eye it was evident that this fragment was from an ancient Greek manuscript. By reporting this to various learned societies it was finally established that this manuscript was the oldest copy of the oldest and most valuable of books, and it rests to-day in the Imperial Library at St. Petersburg. The point is if Tischendorf had not reported to his learned society, if he had not formed the channel for the flowing of that knowledge to the world of scientific scholarship, this priceless treasure would still be hidden in the dusty alcoves of its lonely cloister.

Gentlemen, how truly this illustrates the probable loss of knowledge of untold medical value that sleeps to-day with the withered dust of some unknown physician or surgeon who allowed his knowledge to perish with his body. And how fortunate it is for mankind, the weary sufferer from many ills, that we have brought into existence that system of medical associations which seeks out and records for all time whatever may be of service to our science. No one can doubt the genuine benefit, in its service to mankind, of the humblest medical society.

To the end that our society may perform with utmost fidelity this vital function, may I be allowed to add that every member should feel a keen desire to preserve and transmit for discussion every idea which even promises to be of value to our fraternity. It is my deliberate judgment that we should not confine our reports or discussions merely to those things of which we have become certain and convinced. It is the scientific habit of mind to investigate those things which even have the merest promise of value. Otherwise, the individual and not the collective judgment of the society would be the standard. Many of the most learned scientific societies in the world will investigate minutely and discuss exhaustively anything out of which there is the faintest hope that they may get a valuable truth. Suffer an example. Rumor of the intelligence of the Elberfeldt horses and the strange concomitant phenomena came to the ears of the scientific world. Did they dismiss the subject as unworthy? I find that almost all of the learned psychological societies of the universities of Europe sent commissions to investigate. Even the great Maetterlinck thought the subject worthy of his lofty genius. To the humble stable of Elberfeld came the proudest sons of learning in the world, the immortals in the kingdom of the mind. This array of learning, these wise men of the West, seeking for light in a manger! What a lesson for us humbler searchers after knowledge! This is that rare virtue we call open-mindedness, the highest quality of those lofty men whose names shine like stars in the long and illustrious annals of scientific research.

There is an illustration, amounting almost to tragedy, of that temper of mind that rejects without debate a proposition which does not appeal to it individually. I have in mind the famous discovery of Galvani. No doubt you are all familiar with the circumstances that led to his astounding discovery. He reports the circumstances to his University faculty. Now here is the point. They scoff. They consider themselves above investigating froglegs, and by that attitude come dangerously near robbing the world of its most important physical discovery. But Galvani, though scoffed at on the street and called "Old Froglegs" by his learned associates, pursues his investigations, perfects the Galvanic battery and gave to the world of Science the wonders, mysteries and achievements of electricity.

I have spoken thus far in elucidation of the statement that our society finds one of its greatest uses as a system of intellectual confluence. Let us turn now to the value of discussion. In seeking to make definite the advantage of discussion we have a fine light thrown upon the subject by the etymology of the term itself. The word discussion is derived from the Latin word discutere, and therefore means to take apart, analyze, dissect, and criticise from every angle and every point of view. McCauley says of discussion: "Men are never so likely to settle a question rightly as when they discuss it freely." The reason for the great value of discussion is not far to seek. The view, or theory, or investigation of an individual is liable to many errors arising from his inability to investigate in all conditions and from every pont of view. For instance, a physician, noting an improvement in a patient after the giving of a certain treatment, may conclude that the value of the treatment is proven, when it is possible that the improvement results from climatic, physical or other conditions peculiar to the individual patient. Clearly the treatment must be tried in different circumstances, upon many different occasions and upon many different patients before we will be able to say that the wisdom of the treatment is finally established. Now, it is just at this point that the value of discussion comes. If a hundred men, from dif-

ferent parts of the world, examine, criticise, and fully and freely discuss the question from every angle, point of view, and personal experience, the truth is very apt to be established either for or against the theory. All errors arising from mere personal and local antagonism and local environment will be eliminated and the result may be confidently relied upon. It is well known to this body of intelligent men that Socrates practised discussion as the fundamental of his process of teaching, saying that thus is truth established. It is surely not necessary to call your attention to the rise in the last century of the process of literary criticism, which is nothing more than discriminating discussion, in the learned world, that has corrected, defined, and established truth in all departments of intellectual activities.

This much must be said in all honesty as a limitation to the statements just made: discussion is valuable only in a company of men who are capable of intellectual detachment, by which I mean freedom from personal interests, prejudices, personal antagonisms and any other quality that prevents the sanest, calmest and most disinterested judgment. The type of man who can discuss rightly is to me very beautiful and very wonderful. He only wants to find the truth. The desire for personal triumph in debate cannot influence his judgment; he cares nothing for being in the majority; he discusses the opinion of his greatest enemy with unwavering justice, as much so as the opinions of his dearest friend; he welcomes difference of opinion because he knows that out of difference of opinion the ultimate truth is born, and in his heart all personal feeling or prejudice or enmity is lost in the presence of the need to find the truth. In the presence of the man who allows personal feeling to enter into his association with his brother physicians, we can have nothing but contempt. In the presence of the calm and exalted man that loves and seeks the true knowledge we stand uncovered. Such a man was Hunter McGuire, and his name has a permanent place in the honorable records of our profession. Such were almost all those men whose names are a part of the heritage of our science. I looked once upon the clouds that wrapped the lesser Alpine hills that were hidden by this somber mantle, but far above them lifted the imperial front of Mount Blanc, king of mountains, undisturbed by the driven mists of the vale, unshaken by the winds, calm and resplendent in his ermine mantle of unmelting snow. There are parts of our nature that become swept by personal feeling and prejudice, by a dark mist; but surely in most of us the love of truth is as Mount Everest, high—exalted against all the winds that blow.

It is a most significant fact that in the world of literary genius, criticism and discussion are invited. Dante invited the criticism of his friends upon works that were to take their place among the immortal products of genius. Bacon, the marvel of information and expression, McCauley and Tolstoy, Hugo and Sue, all these sons of light invited the discussion and criticism of their friends. And Shakespeare, who shines among the sons of light as shines a star above the glowworms in the night, invited the keen edge of criticism from his illustrious tavern companions. In the field of art Reubens, Van Dyke, Leonardo, Rembrandt, and Raphael uncovered their immortal work before the cold scrutiny of those who could see the fault of line and color. And if these sensitive men bared the product of their toil, dearer to them than life, to the discriminating criticism of other eyes, surely we, though untouched by the flame of their genius, may still be their peers in sublimity of spirit. We, too, in the words of Tennyson, "May follow knowledge like a sinking star beyond the utmost bounds of human thought."

We turn now to that advantage of medical associations that I will call cooperation. No man here needs to be told the meaning of this term. The world of the twentieth century is a commentary upon it; the advancement of mankind is an illustration of it. Anthropology is in a way only the story of the evolution of cooperation in human history. The mysterious Maker of this material universe laid the pattern deep in the nature of all created things. A rose is countless myriads of individual cells, yet so perfect is their cooperation that to us it is one single deep red rose. And so throughout this stupendous miracle and mystery of being the law of cooperation runs in unbroken consistency. Gentlemen, the world has found that there are tasks which one man cannot do alone; the day of isolated individual labor is forever gone. There are also tasks in our world of medicine which no man can accomplish alone. Some of us know the sorrow of a failure, but what one cannot do, all can do; where one fails, many succeed; individual effort against the great tasks are as a stone tossed by a child against the barren cliffs of Mount Mitchell. But the united strength of men could clear man's path even of that giant mountain.

Let us be more specific. You cannot bring a nation to pass progressive laws for health and sanitation, nor can I. But united, the cooperative brotherhood of physicians can bring any reasonable legal status to pass. What is it we cannot do if we deliver the full strength of our united purpose at one point? We have but to tell over our achievements in the past to know what we may accomplish in the future if we perfect our co-operative strength.

This perfected cooperation must come out of our willingness to work sympathetically with one another. We cannot all be friends, we cannot understand one another fully. But we can prevent our personal feeling from entering into our association, we can work side by side, we can estimate each other in our points of strength and not our points of weakness. Our cooperative endeavor will remove many misunderstandings and we will come to know each other better and like each other more. I found in wandering about the world, by the Tiber, by the Ganges, by the Yangtse Kiang, by the Nile, and by the Canton, that all barriers break down at last when we have touched elbows even with an alien people. As I have said, sympathetic cooperation levels all barriers at last. Many friendships are born in our heart in these associations and some of us have found in such associations those friendships which Hugo says "Is one of the few pearls to be found in the shadowy folds of life."

Cooperation! What a word! Each working with all, and all working with each. Can any one doubt that we shall win our battle against low standards, indifferent laws and deadly disease, if all work as one.

Let us now consider the value of publicity as one of the advantages of medical associations. You will recall that in the beginning of this address I made use of the figure of the circulation of a drop of rain. I left the figure purposely incomplete.

That drop of rain must return to the forest, the flower, the field, the river, bearing in its arms the answer to Earth's parched lips. So, also, our task is not merely to gather knowledge but to distribute it, corrected, validated and certain, to all the needful world. How shall this be done? By leaving merely on our records here the results of our investigations? Clearly not. Medical truth must have some process of distribution by which our results may be known to those who have not the good fortune to attend our meetings. The medical journal is the bulletin board, the voice of your endeavors.

In general it may be said that the advantageous functions of the medical journal are two: distribution of medical knowledge, and a permanent archive of medical evolution. As a means of distribution of medical discoveries and advancement, the medical journal cannot be overestimated. By their combined interlacing and interlocking with associations the distribution of medical knowledge is greatly strengthened.

The second vital function of the medical journal is the preservation, as a record, of medical advancement. All literature has this function. In point of fact, we might define literature as the process by which the thought of all men is preserved for the use of each man, the thought of all generations preserved for the use of each generation. It is by the process of literature that one is able to know and associate with the great souls of all time. Through the gateway of your library, you can sail the seas with Jason, battle with Ulysses on the windy plains of Troy, walk with Virgil and Homer along the heights, sing with Dante and Burns, look at the morning skies with Turner, think with Emerson and Kant, and die at the stake with martyrs and the emancipators of all time. So, in our medical records, may we learn at the feet of the great seers of our science, and preserve the light with which they illumined the night of man's suffering until all shadows shall flee at last before the oncoming morning of man's full physical emancipation.

GONORRHEA IN WOMEN.

By WILLIAM J. ROBINSON, M.D.,

NEW YORK.

CHIEF OF THE DEPARTMENT OF GENITO-URINARY DISEASES AND DERMATOLOGY, BRONX HOSPITAL AND DISPENSARY; EDITOR OF THE "AMERICAN JOURNAL OF UROLOGY, VENEREAL AND SEXUAL DISEASES," "THE CRITIC AND GUIDE," ETC.

WHEN a man has gonorrhea he knows it. While (having learned long ago not to be dogmatic about anything in medicine) I do not deny the possibility of a symptomless or practically symptomless gonorrheal urethritis in the male, still such cases, if at all existent, must be extremely rare. This is not, however, the case with women. A woman may go through an acute gonorrhea from beginning to end, without knowing it, may have a chronic gonorrhea for years without being aware of its existence, often sincerely believing that she is perfectly well. A man is not used to having pains or burning in his urethra, nor is he used to having any discharge from it. At the least pain or scalding, or the least appearance of discharge, he knows there is something wrong with him. The urethra when infected in women does not give as severe symptoms as does inflammation of the urethra in men, and besides in many cases the female urethra escapes infection, the infection being limited to the cervix alone or to the cervix and Bartholin's glands.

A woman is used to pains, the premenstrual pains with which many of them suffer are severer than the pains caused by the gonorrheal infection; and they often have a leucorrheal discharge of greater or lesser degree. An increase in the amount of secretion or in its color and consistency does not attract their attention. It is for this reason that many women harbor the gonococcus for months before applying to a physician, and some of them never apply at all. It is as a rule when the discharge is very profuse, offensive and irritating, when urination is painful and burning, or when there is a sharp salpingeal attack, that the physician's aid is invoked.

I repeat that many women go through life with a chronic gonorrheal cervicitis, with an abundant discharge containing numerous gonococci, and use no treatment except an occasional douche, because they are under the impression that they are suffering from the ordinary leucorrhea or "whites" (just as if leucorrhea itself did not require intelligent medical treatment).

I do not wish to be understood as claiming that gonorrhea in the female is always of a mild character, pursuing a subacute or symptomless course. I mean to say that such are the vast majority of cases which present themselves to the physician who has a "respectable" practice. In the vast majority of cases of respectable married women the disease pursues such a subacute course. Why? Because in them the infection when it takes place is usually the result of *chronic* gonorrhea in the husband. No half-way respectable man will enter matrimony when suffering with an acute gonorrhea, and only an exceptionally brutal or weak-minded husband, who straying from the path of marital fidelity, has acquired an acute gonorrhea, will continue to have relations with his wife. And here is the point I wish to make. When the infecting man is suffering with a chronic gonorrhea, the infection in the woman *usually* pursues a subacute or chronic course. But when the man has an acute gonorrhea, then the infection in the woman may from the very beginning assume a superacute, even fulminant character. And the rapidity with which the infection may show itself is remarkable. While several days usually elapse between the infecting intercourse and the first symptoms, there are cases in which the latter show themselves in twenty-four hours, and I have had a case where the bride, a girl of twenty-one, had her first intercourse at midnight, and the following noon she began to complain of burning, irritation, scalding urination, etc. In short, the symptoms showed themselves in twelve hours after the infecting intercourse. In her case the gonorrhea proved of a virulent character; the contributing factors were the frequent repetition of the act during the night (five or six times) and the violence with which it was performed. The defloration, which leaves an open raw wound, was also a contributing factor in this case, as it is in many other cases.

While it usually takes months for a salpingitis to develop as a result of gonorrheal infection, there are cases in which distinct symptoms of inflammation of the Fallopian tubes may develop within a few days, or even *within a few hours* after an infecting intercourse. In such cases we are forced to believe in the suction action of the uterus. It is impossible to believe that the infection reached the Fallopian tubes by continuous extension, within such a short period. It is more plausible to believe

that the infection took place by the infecting, gonococci-containing material being sucked up into the uterus and into the Fallopian tubes. This appears to be more likely from the fact that a gonorrheal salpingitis may exist without an intervening endometritis or metritis.

The symptoms in an acute or superacute case of gonorrhea may be very severe. Within several days after an infecting intercourse, and sometimes within several hours, the latter particularly in young virgin brides, and still more particularly if the act is performed stormily and repeatedly, the woman begins to complain—or if not to complain, then to experience, because many of them do not complain until their condition becomes unbearable—of a burning and itching in the vulva and vaginal introitus, of frequent urination, accompanied by strangury, and a scalding sensation. A discharge soon makes its appearance, which according to the severity of the case may be creamy, cream-yellow or greenish. It may possess little odor or be extremely offensive. It is often very irritating, eroding the skin with which it comes in contact and causing pruritus and intertrigo around the genitals, anus, thighs, etc. If proper cleanliness is not observed, the infecting discharge may invade the anus and a gonorrheal proctitis be the result. There is usually an elevation of temperature, 100 to 102° F., there may also be a chill, and the feeling of general malaise may be quite pronounced. If the infection involves also the Fallopian tubes, then all the general symptoms may be greatly aggravated. The chill may be quite severe, the temperature may go up to 103° or even 104° F., the abdomen is tender, and the feeling of malaise may be so severe as to create apprehension of a general peritonitis.

The diagnosis of an acute or superacute case of gonorrhea in the female presents no difficulties. The history and the symptoms as related by the patient are alone sufficient. Inspection of the genitals, covered with pus, the introduction of a speculum, which shows us an inflamed eroded cervix, bleeding at the slightest touch, and bathed in pus which oozes from its external os, make the diagnosis certain. No bacteriological examination is necessary.

Treatment.—I know of no condition in medicine where *noli nocere* is more important that in treating gonorrhea of the female. It is just as important to know what not to do and not to do it as it is to know what to do and to do it. In other words, negative treatment is here as important as positive treatment. In fact, abstaining from doing certain things is often the most important part of the treatment.

The great, the paramount point in treating gonorrhea in women is to prevent the disease from passing the internal os and spreading through the endometrium into the tubes, and from there into the ovaries and peritoneum. As long as we can keep the gonorrheal process limited to the cervix and the external genitals, gonorrhea is not a terrible disease. We can handle it without great difficulty, and cure it eventually, though the time required for a cure may in some cases be exasperatingly long. It is when the gonorrheal process is extended above the internal os that we become helpless. For after the process has involved the endometrium and the Fallopian tubes there is no medical treatment; there is only expectant and surgical treatment, which is of course no treatment at all in the true sense of the word. Removing the tubes may be necessary to save the patient's life, but to cut out an organ is not to cure it.

Unfortunately, it is here that physicians have sinned most pitifully. I have no hesitation in saying—it is painful to say it, but nothing is gained by hiding the truth—that a large percentage of cases of endometritis and metritis, salpingitis, and peritonitis, that thousands and thousands of cases requiring surgical interference are due directly to the physician's well-meant energetic treatment. The introduction of syringes and probes into the cervix, the scraping and cauterizing with strong caustic solutions, are in many instances directly responsible for the extension of the inflammation and for the aggravation of the patient's condition. Those who know anything about the treatment of gonorrhea in women and are not obsessed by the *furor operandi*, know that we get the best results by the gentlest methods and mildest applications.

I consider these prefatory remarks of extreme importance, for until the physician is imbued with the feeling, saturated with the conviction, that brutality is not a necessary element in the treatment of gonorrhea, that too energetic treatment is often injurious instead of beneficial, that the uterine cavity must at all hazards be protected from an extension of the inflammation, and that he at least must not be the causative factor of that extension; until he is convinced of all these things he is not a safe person to undertake the treatment of a case of gonorrhea in a woman.

General Treatment.—The general treatment of acute gonorrhea in the female can be expressed in one word or phrase: rest, taking it easy. If we wish to avoid a salpingitis or extension of the inflammation above the internal os, this is a *conditio sine qua non.* It is unfortunate that many women, and respectable married women at that, still must keep on doing their household work or other heavy work. Where it is unavoidable it is unavoidable, and that is all there is to it, but the proper thing would be to put the woman to bed, or at least keep her in her room for a couple of weeks and have her take things very easy.

Where there is a considerable rise in temperature or symptoms of salpingitis seem to be threatening, then putting the patient to bed is imperative, and applying an ice-bag to the abdomen is very useful.

Coitus must be absolutely interdicted. One can think of nothing more harmful, more dangerous, than coitus for a woman affected with gonorrhea. Intercourse is bad for a male gonorrheic patient, but it is very much more dangerous for a female gonorrheic patient. It not only aggravates the existing condition, increasing the inflammation in the vulva, urethra, and cervix, but it is about the surest way to cause a salpingitis. I have known cases which were progressing very nicely, which were on the point of recovery, but which became suddenly aggravated and in which symptoms of salpingitis became evident immediately after coitus. So this must be forbidden absolutely in all acute and subacute cases of gonorrhea. No exceptions can be permitted. Whether this extension of the inflammation is due simply to the engorgement of the uterus and other genital parts induced by the coitus or to a certain suction and peristaltic action of the uterus is immaterial. Both may be causative factors. The fact remains that coitus is a dangerous procedure, which may lead to a fatal issue, for a woman suffering with acute or subacute gonorrhea.

A man who forces a woman in such condition to submit to intercourse is a criminal brute, and the woman who submits to it is a pitiful slave. And still the woman is often forced to submit to it, the husband thinking that if he uses a condom and is not too violent he has done everything necessary to protect himself and her.

As far as the diet is concerned, little or no change need be made in it if the urethra is not involved. Spices and alcohol, however, are best omitted, as they do perhaps cause congestion of the genitalia, and thus aggravate the condition. But where there is a urethritis practically the same restrictions are indicated as in gonorrhea of the male.

As far as internal treatment is concerned, none is necessary unless the urethra is involved. When the urethra is involved and urination is painful, then we may give the same balsams, hyoscyamus and alkalies as we do in urethritis of the male.

Local Treatment.—If the local treatment in male urethritis is important, it is much more so in gonorrhea of the female. In fact, it is the only part of the treatment from which definite results can be obtained, the internal treatment being merely occasional and auxiliary. The treatment to be successful must be of two kinds; one administered by the physician, the other administered by the patient, or to the patient, in her home. The home treatment consists in the use of injections and suppositories. The medical treatment, that is, the treatment on the part of the physician, consists in local applications, that is, in swabbing and painting the parts, and occasionally in cauterizing. Both parts of the treatment are necessary, as they supplement each other.

As stated before, the home treatment consists in the use of vaginal douches and suppositories. The injections that I prefer to all others are iodine, lactic acid, and a combination of alum, zinc sulphate, and copper sulphate. Where the discharge is very profuse the injections should be given as often as four times a day. After the discharge becomes less profuse, twice a day and then once a day is sufficient. The iodine injections are made by adding one tablespoonful of tincture of iodine to two quarts of hot water. In some cases this is too irritating, and we may commence with a teaspoonful to two quarts of water. The lactic acid is used in the strength of 1-500 to 1-1,000. The alum, zinc, copper combination has the following formula:

Aluminis,	℥iv
Zinci sulphatis,	℥i
Cupri sulphatis,	℥iv

Sig. Tablespoonful to 1 or 2 quarts of water.

The injections or douches should invariably be taken in the recumbent position, the patient lying flat on her back on a flat douche pan. It is better when the buttocks are raised, so that they are on a higher level than the rest of the body. The injection is given very slowly, the fountain syringe hanging but high enough to permit the liquid to run out. After each injection the patient should remain for half an hour, or at least fifteen minutes, flat on her back. This permits some of the liquid that remains in the vagina to bathe the vaginal walls and the cervix. In the average case I order two vaginal douches a day: in the morning, either the iodine or the lactic acid solution; in the evening the astringent powder. Where three or four injections a day are ordered they are used in alternation. There is no doubt as to the good effect of these injections. Not only do they keep the parts clean and mechanically remove the discharge, which is such a good nutrient medium for the various saprophytic bacteria, but they also have a gonocidal effect, heal erosions and congestions, and help materially the doctor's work.

In some severe cases I also order suppositories, one suppository to be introduced at night. The suppositories usually contain as their active constituent either protargol or the lactic acid bacillus. The formulas of these suppositories are as follows:

℞ Protargol,	gr. v
Olei Theobromatis,	℥i
M.f. suppos. ovale vel glob.,	No. i
D. Tal. Dos.,	No. xii

Sig. One at night, inserted high up in the vagina.

℞ Bac. Bulgaricus Tablets	gr. x
Ol. Theobromatis	gr. l
M.f. Suppos.	No. i
D. Tal. Dos.	No. xij

The tablets may also be inserted in substance.

The Doctor's Treatment.—The patient comes to the office always immediately after having taken a thorough douche. The only time the douche is left out is when the doctor wants to make a bacteriological examination of the secretions. He wipes off the vulva, examines carefully for any inflamed points or erosions, and if there are any he touches them with silver nitrate 10 to 50 per cent., or even with the silver nitrate stick. The ducts of Bartholin's glands are examined carefully, an attempt is made to express any pus, and if found necessary they are cauterized with a thin probe or a 10 per cent. silver nitrate solution is injected into them by means of a hypodermic syringe with a blunted needle. The urethra is next examined, and if affected is swabbed with a 5 to 10 per cent. silver nitrate solution. As a rule the urethra responds to treatment very readily. I have no use for any urethral bougies or suppositories in women any more than I have for them in men. The vagina is next examined with a speculum and a good light, and erosions, if any, are touched with silver nitrate solution, 10 per cent., or tincture of iodine full strength. Lactic acid, full strength, is also a good application.

We then come to the cervix, which is the most important part of the treatment. We wipe it off as carefully as we can, introduce several cotton-wound probes and try to remove the cervical plug. The entire cervix is then painted with tincture of iodine, and a thin cotton swab dipped into tincture of iodine is gently introduced into the os. Care is taken not to pass the internal os, though if it should pass the danger of extension of the infection would be nil, or practically nil. Iodine is one of the best agents we have in treating gonorrhea in the female, and while I still use silver nitrate applications to the vagina, vulva, and urethra, as far as the cervix is concerned I limit myself exclusively to iodine. My results have been much better since exchanging silver nitrate for iodine, because silver nitrate denudes the delicate surface of the cervix, and may perhaps be influential in causing an extension of the inflammation. Instead of a probe a thin, long uterine syringe may be used and a few drops of tincture of iodine may be deposited in the cervix.

When the infection has spread into the endometrium and the tubes then it really ceases to be

a genitourinary and becomes a gynecological case. But the gynecological surgeon can do medicinally no more than the ordinary physician unless it is a case which demands operation. The proper treatment of endometritis and salpingitis is rest, hot or cold applications by means of compresses or poultices to the abdomen, and tampons of gauze saturated in glycerite of boroglycerin or ichthyolglycerin or thigenol-glycerin. That is all we can do and that is all we should do. Injecting or swabbing the uterus with caustic or strong antiseptic applications, scraping, or curetting the uterus, all these are brutal and useless procedures; not only useless but injurious. They may do good in some cases, but the cases in which they do harm are so much in preponderance that no conscientious physician should employ them. We can never be sure of removing all the germs by these measures, while we are pretty sure to cause their further spread and development and to aggravate the inflammation. Curetting is not abused so much now as it was formerly, but it is still practised ten times more often than it should be. Hot baths, particularly pretty concentrated sea salt baths, are useful in aiding the absorption of exudates. And I repeat that unless the case is a distinctly surgical case, demanding surgical intervention, this is all the gynecologist, genitourinary surgeon, or general practitioner can do. An attempt to do more is not generally dictated by a desire to benefit the patient.

Vaccinotherapy.—The author is not an enthusiast about vaccine in gonorrheal conditions. In urethritis, for instance, male or female, he considers it useless; and in many other conditions in which it is being used very extensively he considers its value very doubtful. Careful investigators who can guard against the *post hoc propter hoc* fallacy are coming to the same conclusion. Nevertheless, in conditions which are not accessible to local treatment, such as salpingitis, we are justified in giving the antigonococcic vaccines and bacterins a thorough trial. In a small percentage of cases they seem to be useful.

12 Mount Morris Park West.

PHYSICAL BASIS FOR MORAL AND MENTAL DEFICIENCIES.

By HENRY M. FRIEDMAN, M.D., LL.M.,

NEW YORK.

ACTING ASSISTANT SURGEON, UNITED STATES PUBLIC HEALTH SERVICE.

It has long been understood that the extreme mental backwardness of the idiot and of the imbecile is not merely an abstract, obscure mental condition, but is most likely due directly to extensive physical changes in the brain tissue. In imbeciles the tissue changes often are very concrete in that they affect the motor areas of the brain and cause gross bodily defects. Likewise in such psychoses as are exemplified by paresis, senile dementia, epileptic insanity, etc., the most apparent causes are physical tissue changes. In the idiopathic psychoses and the lesser mental deficiencies no tissue lesions are found even with the microscope, and they are ascribed to inherent, obscure mental infirmities of the brain. On the other hand, among the backward population of schools and institutions there are a great many who have physical and sensory defects, not organic in nature, which when discovered and remedied clear up or improve a great many of them mentally. "Mental dullness may be caused by a variety of pathological conditions far removed from the immediate center of intelligence, and it is the imperative duty of the educators to locate these causes and when possible remove them, instead of shirking their responsibility by grouping all backward children together."[1, 2]

Physical and Sensory Causes.—Poor physical condition, malnutrition, anemia, and the intoxications interfere with brain nourishment and cause diminished brain action. Impairment of the special senses, diseases or disorders of the ductless glands, and certain other specific conditions are in more direct causal relation with mental deficiencies than the general conditions. The former act either by depriving the mind of the stimuli from without, necessary to brain fertilization, and without which even the richest brain soil must remain sterile; by the lack or the overabundance of certain so-called internal secretions vital to physical and mental well-being, or by the diverting influence, so to say, of other abnormal manifestations.

Ocular.—Of prime importance among the sensory causes of mental dulness are ocular defects of one kind or another. In most individuals visual memory is strongest and the first to appear, and defects in the visual channels do the greatest damage to the mind—and the auditory channels are not far behind. Children suffer a great deal from eyestrain due either to the effect on the eye muscle of general muscular underdevelopment, or to a local underdevelopment of the eye muscles alone, and which becomes manifest as soon as school work is commenced.[3] Unless the muscular defect of the eye is nervous or central in origin it is hardly likely to be purely a local muscular weakness. Indeed, eyestrain is commonly associated with the poorly developed physically and with the neurotic. In the larger muscles of the body variations in the strength or in the tone of the individual muscles, unless extreme, are not noticeable, but the muscles of the eye are so delicate that the slightest variation has a bad effect upon the adjustments of the eye. The constant strain of trying to overcome the muscular inequilibrium, especially when trying to focus for near work, causes the many neurotic manifestations of this type of backward child. At times the persistent attempts to continue the focus on reading matter results in many and apparently peculiar mental syndromes such as the omission of words in sequence and the substitution of words or letters not in that part of the text. It is caused by the wandering of the eye to other places when it can no longer maintain the focus, and in consequence, the attention. Under these difficulties it is not surprising that reading is shunned, learning is difficult, assimilation almost impossible, and mental dullness inevitable. The proper direction and easy adjustment of vision to the needs of the occasion are interpreted by the facial expression, and in eyestrain there is a blank expression of the face. Profound eyestrain has been found to accompany insanity and epilepsy, especially in those with a hereditarily unstable nervous system, and to clear up completely on correction.[4]

Pure errors of refraction are not only of themselves prolific causes of eyestrain, but they prevent the child from ever getting a true sharp image of the objects before it, and its world is in proportion untrue. The refractive errors of chief importance are hyperopia and astigmatism—and they are frequently found together. They are the least apparent and are oftenest overlooked, because

vision for distance is usually very good, and they have no difficulty in passing the only used test—the Snellen card. Yet they produce great discomfort and children cannot read even for an inconsiderable period without tiring. As soon as they recognize the ill effects of reading they shirk it. Often these refractive errors give rise to tics, twitchings, convulsive movements, torticollis, and curvature of the spine. The choreic and the convulsive movements combined with the attendant dullness have been confused with imbecility, only to disappear entirely on correction of the refractive errors.[5]

With myopia we have a defect more easily discovered, and one which gives the least amount of trouble unless the defect is so high that the child can practically see nothing. Myopia rarely causes eyestrain. While myopic children are often the brightest, their hyperopic or astigmatic classmates of equal mental capacity are inattentive and are branded defectives. High myopia is rarely left uncorrected and hence does not operate in the causation of mental defects, but unfortunately it receives the whole attention of the school physicians and nurses, while the more momentous errors are overlooked. Too much significance is accorded the standard test card for distance and too little to the more vital errors not of distance. "The action of the malformed eye begets disease of the eye, diminution of cerebral action, of feelings, and of nutrition."[5, 6]

The mental inferiority attributed to the albinos—the pink eyed—is due almost entirely to the effect of the failure of vision. The absence of pigmentation in the choroid changes the eye from a camera obscura to a camera lucida, prevents the absorption of the light rays, causes photophobia, and allows little or no work to be done under light. In early times this bat-like or owl-like propensity brought them a great deal of opprobrium and even persecution. While the visual defect cannot often be corrected, dimmed glasses will remedy the photophobia and allow the victims to read and to learn.

Auditory.—Auditory defects, whether central or nervous, or local and due directly to ear diseases, or indirectly to adenoids, nasal obstructions, or narrowing of the pharyngeal vault, deprive the mind of this pathway to it, and particularly of the stimulation necessary for the development of auditory memory. The deaf mute, though deprived of this pathway and of the mental exercise furnished by speech, is yet rescued from mental oblivion by the still modern methods of training through the patent senses. In the very young mute it is well-nigh impossible to differentiate between a negative mentality and a potentially normal one. With hearing lost, though possessing central and motor power of speech, children may remain deaf-mutes because they do not hear spoken language. Indeed, there are instances where, though the power of hearing and speech are normal, the child does not speak simply because being deprived of the company of other children it does not hear sufficient spoken language spoken to learn. Children learn to speak much sooner in the company of other children. It is important to recognize and to separate the various auditory-speech defects, and not to confound them with each other or with idiopathic mental deficiency, lest curable cases be set adrift.

Nasopharyngeal.—Nasal obstructions, adenoids, pharyngeal constriction, and tonsillar hypertrophies produce mouth breathing, difficulty and diminution of the respiratory function, restlessness and sleeplessness, with anemia, malnutrition, chest deformities, and the general lack of physical development, and are accompanied by neurotic tendencies and mental dulness. The usual concomitant, ear complications, reduce the hearing even to total deafness. These children are easily recognized on inspection from their typically dull facial expression, open mouths and protruding lips, yet the expression does not differ so very much from the dulness and apathy of the pure defectives, especially when the two conditions coexist, perhaps one the cause of the other. Removal of the obstructions and the treatment of the ear complications restore the hearing, the normal expression, and the intelligence.

Often, however, the removal of the adenoid vegetations does not remedy the conditions, and it is found that the vegetations were not even large enough to warrant removal. In these the pharyngeal vault is found so narrow that there is obstruction even without the slightest evidences of adenoid vegetations. There is usually a Gothic vaulting of the palatal arch, and a narrowing and an obstruction of the nasal passages, in most cases taking the form of deflections of the septum. The pharyngeal condition is developmental, probably hereditary and racial. The higher the plane of a race or of an individual the more does the cranial vault develop at the expense of the face, and the greater the tendency to obstruction. Even with very severe bony malformations the negro with his smaller cranium and larger face has little annoyance from nasal obstruction.[7] Unless some other remedy than the here ineffective intranasal operations is devised these cases remain permanently defective. Rapid separation of the maxillæ at the sutures by methods of orthodontia have been tried with much success if commenced early.[8]

Enlarged tonsils are local obstructions to the air passages, besides exposing a very large surface to infections; and in this respect they are considered to be a chief factor in the etiology of valvular disease in children. They cause inattention, restlessness and dulness. Removal is a comparatively simple procedure, and usually brings relief. Surgically, the indications would seem to be the entire removal, the enucleation, of the tonsils. Medically, it may be best to leave some of the gland tissue *in situ* in order that the gland may functionate with respect to a possible internal secretion. And, indeed, the old tonsillotomy is again gaining favor; it removes the obstruction, and that is, after all, what is particularly sought.

Genital.—Phimois and paraphimosis, in all likelihood in the female as well as in the male, are sources of irritation which militate against the mental and physical well-being of the child. They cause inattention and restlessness as well as bad sexual habits, especially masturbation, and help to divert the attention of the child from the proper channels for its development. Circumcision in the male is an easily applied remedy, and should be universally adopted.

Neurotic.—Of the neurotic manifestations which seem to bear a close relation to amentia of one degree or another, chorea is the most important and the most common. Chorea can last such an inordinately long time that it gives rise to the suspicion that one deals rather with a chronic and perhaps a permanent mental and nervous condition, than with real chorea. There is loss of memory and inability for application to studies; the grim-

aces and the frequent meaningless and unprovoked laughter may very easily be mistaken for a very profound mental deficiency. The irritability, instablity, and mischievousness are not unlike the temperaments of the "instabile" feebleminded, who while inattentive to, and backward in, the studies yet possess a sort of primitive brightness, cunningness, or precociousness. The more these choreic children are made to apply themselves to study the worse become their mental and nervous symptoms. This downward progress but confirms the erroneous impression that one deals with an idiopathic form of mental enfeeblement. Feebleminded children grow feebler in direct proportion with their age and the grade of their studies; older children naturally show defect more than younger ones—at least by contrast.

Tics, habit spasms, epileptic manifestations, and migraine attacks are nervous manifestations usually found engrafted on a weak heredity. They prevent attention, retard education and mental development. Migraine in older children and in adults is related to cyclic vomiting in young children; the cause in either is not known, but is believed to be either an hereditary constitutional inferiority, faulty metabolism, or a constriction of the foramen of Munro.

The so-called nervous children are usually very much under par physically, and often above par mentally. Their brightness does not, however, possess substantial stability; it is transitory, short lived, and very prone to give way in later life to the development psychoses, especially to dementia præcox, or to distinct mental enfeeblement. They are better described as facetious, cunning, or sharp, than bright. The mental spurts that these children do perform are nothing more than flickers under the lash of their nervous irritation; and it is not long before these apparently bright children succumb to physical and mental exhaustion.

Speech Defects.—Speech defects are largely neurotic manifestations, and are considered stigmata of degeneration; they retard mental development either through a communication of the motor defect back to the brain or through the hindrance to the facility of expression so necessary to liberal mental advancement. Things are remembered much more easily when repeated or expressed than otherwise, since the action of speech sets in motion and exercises many different nervous lines. Of this aid the stammerer is deprived. Older children become very sensitive of their defect and hesitate to take part in expressions or discussions. The fear of talking makes the severer cases little better than mutes—and worse off because they do not get the association or the attention of the latter. Stammering is curable and there is no excuse for its neglect.

Muscular Weakness.—Weak muscles, especially the muscles controlling the hands and fingers, and general muscular incoordination, often go hand in hand with mental weakness; and development of these muscles and their coordination develops the motor centers in the brain, and they in turn develop or stimulate to development the mental centers. It is for this reason that writing is such an important phase of teaching. "The training of the hand is the chief agent in promoting mental activity."[5] Motor methods of teaching, while perhaps the most primitive, are, nevertheless, the easiest for the child; and if deprived at the start of this method of coming in contact with environment, it will lose this influence in mental development. The right handedness of most people is an illustration of the connection between the muscular movement in writing and in declamation, and the speech center. The center of speech is closely in contact with the motor centers of the right hand. Either right sided muscular movement is responsible for the development of the speech center or the location and influence of the speech center is responsible for righthandedness. The value of muscular exercise and training in the school curriculum is not merely physical, but mental as well. The great value of muscular movement exercises in the training of defectives is now well established. Aphasia victims can learn to speak sooner by making them write. The connection of this defect with the mind is shown by the amount of mental deficiency among them, both when the condition is sensory or motor; and it is surprising that they are not more defective. The motor method of teaching is the easiest and the best, next is the visual and lastly the auditory.

Glandular.—While the mechanism, the function or the place in the human economy of the ductless glands are little understood, the results of overdevelopment and oversecretion, underdevelopment and diminished secretion or total absence of the glands, are oftentimes well marked; and of these results the mental disturbances and mental enfeeblement are of no little importance. Abnormal thyroid conditions give the most marked and the most characteristic symptoms. The cretinoid type of defective differs in no wise mentally from the idiopathic types, but unless too profound or allowed to go too long so that tissue damage has occurred, yields to thyroid medication. The deficiency or removal of the thyroid in later life produces an analogous mental and physical state as in the congenital form of deprivation, and is called myxedema. There is destruction and chromatolysis of the nerve cells and processes, and as a result the mental dulness, apathy, and deficiency may become extremely marked. Overfunctionation of the thyroid, on the other hand, causes extreme mental irritability, hysterical manifestations, excitation, and even manic excitation. In them there is rather a mental exaltation and precocity, than dulness or apathy. They are said to have a "chorea of ideas." These are in effect the mental manifestations of Graves' disease.

The absence, the arrest of development, or the removal of the testicles or ovaries causes a lowering of intelligence, memory, and general mental efficiency, besides the characteristic facial appearance of male castrates. Castration of animals produces shrinkage of the cerebral and cerebellar tissues and even of the superimposed brain case. Eunuchs and skopzies—members of Russian sects which have castration as a religious rite—are deficient in intelligence, in courage, and in morality, and they are indolent, avaricious, and cruel. The mental and nervous disturbances following the complete removal of the ovaries is now so well appreciated that whenever possible a piece of ovary, no matter how small, is left *in situ* to supply the internal secretion and to anticipate nervous and mental disturbances. Overdevelopment or precocious sexual development in children often goes hand in hand with mental precocity, but the training, education, environment, and companionship must therefore be carefully guarded lest this mental precocity be utilized in criminal rather than in upright ways.

The disturbances of function accompanying pituitary abnormalities produce, besides the well-known bony enlargement of acromegaly, pressure on the optic nerve, or psychic disorders from pressure of the thickening bone on the brain tissue, loss of memory, slowness of the mental processes, general mental depression, and mental enfeeblement.

In Addison's disease, a disease of the adrenals, probably of tuberculous origin, there is apathy, loss of memory, mental depression, dementia, mental imbecility of varying degrees, together with weakness of the special senses.

While in the advanced gland conditions there is little room for error in diagnonsis, it is not unlikely that in the early stages the mental deterioration may be the only symptoms, and then perhaps emphasized out of proportion to the lesion. If the frequency of association of somatic ills with the mental means anything, it means that many heretofore considered idiopathic mental or moral affections are quite concrete, and that it is imperative in every case to look for some tangible physical, physiological or sensory basis for the mental embarrassment. Many mental deficiencies can be improved by modern educational methods adapted to these classes of cases, even when no removable basis is discovered.

Sensorial Deficiencies.—The development of the nervous cells of the brain, and of intelligence, depends, then, for its proper and orderly progress first, upon a generally normally acting organism; second, upon the ability of the organism to receive from the outside, through the special or "unspecial" senses, the stimuli necessary for brain fertilization, and lastly the quality and the quantity of these stimuli. Were one born with a perfectly normal brain, but with all the known special or unknown unspecial senses not patent, one would be a complete idiot. The ability of the brain to receive stimuli depends upon the patency of the senses, and their ability to carry in the stimuli in sufficient quantities, without alteration and with sufficient alacrity. The quality and the quantity of the stimuli depend upon environment, education and training in their broadest sense.

Defects of Association.—Even after reaching the brain through patent sensory paths, in sufficient quantity and of good quality, the impulses would be of no value to the mind except for the good offices of the association or projection fibers. The higher forms of efficiency-conception, reasoning power, judgment and general intellect, depend upon their specialized and orderly action. The index of education is the quantity and quality of the percepts and more internal concepts and the number of their associative combinations. "No mind is more poorly trained than one which is crowded with items of information without an *inner relation* between them." And this is the state of mind of a great many trained, educated or "normal" defectives—they lack association and correlation. The power of association is the first to show lapse, defect, or disorder, and is an important diagnostic feature in these conditions. Defects and disorders of a more subtle character, and so ill defined as to defy identification, are caused by breaks in continuity or "short circuiting" in one or more groups of association paths. There are many mental variations from the normal due to some slight or some complex error in association combination—but the combination is unknown.

Unspecial Senses.—Ordinarily we look to the special senses as embracing all the paths of ingress to the mind, yet there must be other sense paths, of some we already have clues, of most of them we know nothing. They exist, nevertheless, and when defective must give rise to the many subtle deviations from the broader intelligence met with in all walks of life. Intelligence is, after all, nothing more than an appreciation of the proper value and relation of things, of facts, of ideas, of impulses—their relations syllogistically; but lacking some of these impulse data all the necessary elements of the syllogism are not present and the reasoning or viewpoint is not normal or logical. Bunyan's "five gateways of the soul" are not, then, the complete list of the senses; recently discovered senses are muscle sense, joint sense, tendon sense, heat sense, cold sense, the sense of pain, organic sensations from internal parts of the body, etc. Who can say that there are not numberless special or unspecial senses, the absence or disorganization of any number or combination of them producing vital mental eccentricities—and perhaps only partial in character or in degree; if severe, easily identified as a distinct mental condition; if slight, appreciated but not identifiable?

Certain senses are brought into being only under special circumstances. The sense or the instinct of life may be a very indifferent or dormant sense till after an attempt at suicide, or during or after serious illness—then it becomes very keen. The sexual sense in women often finds expression, apparently, only under certain circumstances—as after childbearing, for example. A great many senses are acting without giving evidences of their action—just as many bodily processes—but make themselves felt during inaction. The senses express themselves in quality, quantity, and intensity, and there may be disorders or defects in any of these respects. The color sense may be partial to certain colors. Hearing may be limited to certain tones, to high or low ones—or to pitch; taste, to various tastes—the sense of smell, likewise. Perception in all senses may be only between certain limits, and stimulations of greater or lesser degrees are not perceived at all. Sensory defects may be partial in numerous ways or degrees, but always leaving an imprint on the mind, however slight. Mental conditions from maldevelopment of brain areas, or from the inoperation of a sense or sense group, when more general than the local defect would justify, are communications by extension to the unaffected areas, or are the ill effects of bad neighbors; or it can be said that the other areas are less efficient because robbed of the association or mediatory help of the defective areas. A very profound condition, even when limited to a certain sense or area, may exert baneful influence over the entire brain and make of the individual a more or less complete defective.

Sensory and Mental Education.—In the normal brain with patent senses, disuse of the mind and lack of education deprive the mind of that exercise necessary for development, the same way as physical exercise is necessary for physical or muscular development. Like the body, the mind may atrophy from the lack of exercise. A great many studies have no material or intellectual value in later life, and, indeed, do not stay in the mind, but they have the effect of mental exercise, and that fully warrants the time spent thereon. "Mental development is not hindered by the deficient growth of the brain, but the brain is retarded in its development by the

absence of all mental activity and excitement." "Paths," which have been considered absolutely impervious, have been opened and widened almost to normal by mental exercise. Defectives have been trained to do most difficult things—music, poetry, translation, etc. An attempt should be made to discover and then to develop the pervious path or natural bent, and that path made to supply the loss to the brain from the impervious ones. Even an expert genius can be created in such a way. The genius-defective, the one-path genius—an individual with a "single track brain," sometimes also designated "learned idiot" or "savant idiot"—collects all the many strands of the mind which themselves separately are too little developed or too weak to be of any value alone, and launches them into the most likely field. The sum of all these undeveloped or undifferentiated or unspecialized strands, which because of their condition are biologically available for use in any place, are far greater than any individual normal or even overdeveloped content. The normal specialized brain powers being differentiated are genetically restricted from use anywhere except in their own particular field, and they cannot be gathered together to do the genius sort of work. Paths reclaimed or newly developed by training can be used to do the work of the defective ones in the same way as is done in tendon and nerve surgery where the good tendons and nerves are made to do also the work of the bad.

Education develops the brain cells; it does not increase them. Education cannot supply missing brain cells. Education and the influence of environment do increase the number of the dendrons, the projection or the association fibers, and allow greater latitude and variation of association and greater mental poise and equilibrium. The mutations and combinations in association increase in direct proportion to the increase of dendrons. The number of the developed or matured cells—that is, the maturation of normal cells—does increase with education probably up to the 40th year, after which heretofore undeveloped cells can no longer develop. This accounts for the mental fixity of age. Maturation of young, immature, and functionless cells is brought about in the course of mental development and is accomplished through and increased by, education. Large numbers of undeveloped cells are found in all adult brains, and it shows that all cells have not been taken up in the formation of the psyche. The number of cells capable of development are commensurate with the possibilities of education. The mental fixity in age, where remote events are vividly recalled while recent ones are not, simply means that in the early and the receptive period of life the brain cells were physically affected by the impressions which remained physical parts of the cells, and therefore retained in memory, while the now old, sclerosed, and unreceptive brain cells can no longer take an impression, and things pass out of memory with the passing of the event. The higher the psychic plane of the individual the smaller is the number of the undeveloped cells. Brain cells governing defective sensory paths are immature, but can be developed through other avenues—which accounts for the apparently universal mental development of the Helen Keller and Laura Bridgeman types. One may be made to learn even through the skin. "How wonderfully it is proven how much the senses are alike at the bottom, and to what point they may supply one another." Cell development is hastened by physical and sensory efficiency and impeded by all impediments of environment. "In persons in different stages of weakmindedness the cells are accordingly defective in size and in number." [10, 1]

Partial Mental Deficiency or Mental Assymetry.—Aside from definite sensory defects of kind, quality, or degree, which may have their effect on the mind, there are mental deficiencies limited to certain conceptions, where no sensory defect is at least apparent. There may be defects of apperception, association, judgment, and discrimination—analytic or synthetic, memory of kind—visual or auditory, and of place, things or events, of suggestibility, of imagery or imagination, introspection, will power, moral consciousness, of personal, race or familial pride or duty, etc., and of any number of combinations. Defectiveness in one or more of these, especially if not marked, need not influence the individual's usefulness. Such defectives are found among college students, teachers, professional men —and in fact, in all walks of life. Some persons have very strong visualizing powers and visual memory, but very poor auditory memory; and if teaching were confined in them to auditory methods, they could derive no benefits from them, would fall behind and soon become backward; whereas, if the visual methods received more emphasis they would remain quite normal. Others may be deficient in both auditory and visual memory, and while the coexistence of both is a serious handicap and indicates constitutional inferiority, yet a great deal can be learned by motor methods of teaching, especially when pupils are strongly motor minded. These learn by action what others learn by seeing and hearing. Motor minded children labor at a great disadvantage with visual and auditory minded classmates. The motor mind and the motor method of teaching are respectively the most primitive and the simplest. The feebleminded, in fact, can be taught little by any but this method, and, indeed, they are taught a great many things by which they become self-supporting.

All teachers have had experience with the beginner at school, where even the apparently normal children were backward in one way or another; some were good readers but very poor writers, others good in mathematics but poor in writing, and so on for all the subjects. Everywhere there is given emphasis to human imperfections and weaknesses.

The early backwardness, in school matters at least, of some of the great men in history is explained on the ground of partial mental deficiency unrecognized and not provided for by the early schoolmasters. When, however, these men were allowed or themselves assumed the liberty of individual methods of mental development, the genius in them promptly rose to the surface. Had they been too long restrained they might have been lost to the world and perhaps been morons. It is said that John Hunter, the anatomist and surgeon, could not learn to read or write till 17; Oliver Goldsmith's teacher said that he was impenetrably stupid; Henry Ward Beecher was deficient in word memory; Wordsworth, Linnæus, Darwin, Newton, Heine, etc., were considered defective school children.[11]

Sensory and Mental Compensation.—It is a common belief that curtailment of one or more of the senses was compensated for by Nature in the enlargement of scope, function, and intensity of one or other of the sensory powers or of the general

mental capacity. The blind, for instance, have been credited with extraordinarily fine tactile sensation and very acute hearing, but this is not corroborated by actual experiment. With the loss of a sense or diminution in its power, the organism is left with fewer senses among whom to divide the limited attention, and their powers are better trained and made capable of keener observation. The sense or senses which came nearest to being able to take the place of the defective one are given better educations. To the organic economy the result is the same no matter in what manner this result is reached. Blind tuners are sought after because they seem to have a finer and more sensitive appreciation of tunes than tuners who see. The blind are said also to possess a "sixth sense" or a "sense of obstacles" with which to perceive and avoid obstructions—and this seems to have practical demonstration.

The physically deformed are likewise credited with greater mental capacity—in spite of the doctrine, *mens sana in corpore sano*. The greater capacity, if present, is usually special, in one line, and is present only because more pressure has been laid on their mental education—even in families where the training of children would be in manual occupations—in order that they may hold their own with the people with whom they are to compete, in spite of their infirmity. In others instead of a generally liberal education being given, a special education, even to the exclusion or neglect of other lines, is commenced very early with such a purpose in view. Inquiry is made into, and attention paid to, the bent or innate capabilities of the child and these fostered and trained to fit them in a field where they can do the most. Such inquiry and attention would be of benefit to all children, and perhaps this would help lower the number of misfits and incompetents in all walks of life.

Moral Deficiency.—The criminal or unmoral tendency may be cited as a definite, though serious example of partial mental deficiency. Frequently criminal and mental conditions are closely associated. It has often been demonstrated that a large part of the criminal population of penal or other institutions is distinctly backward mentally and physically. The moral sense or conception does not differ materially from other conceptions, and it is in this conception that the criminal is found wanting—perhaps brought about through the absence or inefficiency of some unknown unspecial sense or some ductless gland.[12] The ammoral may be low enough to be a moral imbecile or idiot, with crimes bestial; or he may be a little higher and be merely a plotter of mischief—a moral "instable;" or he may even be a genius in crime, with mental and physical development of the highest, but morally the lowest. The defect in moral conception need not be universal, so as to make one devoid of any moral sense or upright tendency. It can be partial in that the individual has a proneness only for certain unsocial acts. He may be a veritable specialist or genius for certain crimes, and a veritable failure in others, which he may be unable to do well or unwilling to do—perhaps, from the moral standpoint. Indeed, most people will consider certain acts honest and moral, and commit them without any qualms of conscience, which even on casual analysis are dishonest. Besides, what is now right may be by a future conception very wrong—but the normal will soon rise to that conception.

Even conceding the somatic basis for crime, environment is yet the exciting cause, and rescue from the temptations of life would often prevent the tendency from becoming manifest, just as guarding from adversity can prevent latent psychopathic tendencies from becoming patent. Under improper environment it is not improbable that a great many now moral individuals would be criminals.[13] The criminal tendencies *per se* are the normal tendencies of primitive races, but these are of no comparative value because aboriginal races are on the whole defective mentally. Aboriginal children can be trained to be as bright or even brighter than civilized children, especially when trained under the same environment, but their mental development is determined by a short period of their lives, and at a very early age they have exhausted their limited supply of gray matter and they stop developing further. The childish tendencies such as wandering, begging, lying, cruelty, etc., are primitive, and the criminal acts of later life, where there has been no proper training or guardianship, are merely accentuations given them by the added mental development. The general tendency to unsocial deportment is atavistic, since the moral sense was absent in the primitive peoples, and their presence now is an evolutionary change and adaptation for purposes of self protection, so as to allow individuals thus protected by the communal moral sense to devote their time to other endeavors instead of merely to self protection. Morality is often more of a special habit than a principle.[1] "The barriers against crime are will power which controls the passions, and sound judgment which allows one to distinguish between right and wrong."[12] To whatever cause the criminal tendency is ascribed—to the lack of moral sense, to habit, to mental or physical defect, to environmental conditions or to atavistic retrogression, the remedy cannot logically be found in punitive therapy.

Age Determinations and Responsibilities.—In every determination of mental efficiency or moral responsibility the age is a pivotal point. Age is a relative and not an absolute consideration. The chronological age means only that one has been in being a certain number of years, and does not convey so definite or so important a meaning as would be conveyed by the anatomical, physiological, or psychological ages. Some children mature very slowly in every respect; others, the precocious, mature very rapidly. In both the chronological ages may be the same, yet it would not be correct to say that the slowly maturing and the precocious child are of the same age, and to charge them with the same mental and moral responsibility. It is difficult, however, to determine with any degree of accuracy the anatomical, physiological, or mental ages. Probably one's own experienced judgment, after careful examination and the consideration of all data, is the best guide to the actual age. Medicolegally such a judgment might not stand, for something more definite is required, based perhaps on some technical observation. Rotch suggested that the carpal bones of the left side show on Rœntgen-ray examination a uniform degree of development in harmony with the general physical development. A table of carpal bone ages could be constructed, which would always tell the truth and could be used as a standard for comparison. This method is not practicable and therefore not much in use.

Mental Age Determinations.—Unless, in using the Binet-Simon test or its modifications, the actual

or anatomicophysiological age is also kept in mind, the comparison of the chonological age of a child with the Binet-Simon standard mental age will not be entirely satisfactory. The scoring used in making mental age computations, in which a child is given added credit for mental age if it succeeds in negotiating some of the problems of the next higher age, or less credit if he fails in some of the problems of the next lower age, and allowing the gains and the losses in the scores to neutralize themselves, can be further modified or corrected for error, according to the actual developmental age. The slowly maturing child receives a handicap; the rapidly maturing or physically precocious child should start on "scratch"—or even behind, according to development. The Rotch table, were it feasible, or one's own judgment of physical age, could be combined with the chronological and mental ages and perhaps a mathematically mean age determined. At any rate children should be started in school according to their actual developmental ages, and not purely according to their chronological ages. In this way the physically precocious child could even be started earlier than at the usual age of admission. On or before admission of a child to school it should undergo a very complete physical examination, as well as a complete mental examination. There should be placed against the child's name the results of these examinations, the likely degrees of physical and mental development, a notation of remedial defects, together with a digested personal and family history. A great deal of disease and defect could in this way be anticipated. After all, a school is a clinic, purposed to develop the immature, and no aid to this purpose should be overlooked.

Legal Responsibility.—A child is *sui juris* and responsible for its acts after reaching a legally determined age. Yet a child above this established chronological age, but below it mentally or physically is not *sui juris*. Children could be brought within the embrace of the juvenile delinquency acts if credited only with their actual or with their mental ages. Perhaps many more infants—not only in the legal sense of minority, but in the actual sense—old in years, but young in mind and body, could be saved from capital punishment, and society would also be saved from the odium of the hangman, at least in these cases. The attachment of psychologists to all courts has been frequently urged, for this ovation, the establishment of the children's courts, as well as the passage of juvenile delinquency acts, are forward steps in modern times.

Every delinquent child should, before being brought before a judicial officer, be examined mentally and physically, its personal, parental, and ancestral history inquired into, as well as an inspection made of its home environment. The results of the physical and mental examinations should be detailed in full, together with a statement of remedial defects, and the general index of the mental and physical development indicated. Where it is found that there are physical, sensory, or mental defects the final disposition of the case should be deferred until after treatment has been completed and time given for reaction. Perhaps treatment could be enforced where entered upon unwillingly by the child or its guardians as a form of "expiation" for the delinquency, as it were. If after treatment there is a cure of the unmoral tendency absolute liberty can be given, or perhaps for a time under probation; if unaffected by treatment, then proper custodial, but not penal care.

Conclusion.—In conclusion it is urged that idiopathic mental or moral deficiencies are idiopathic only because science is yet ignorant of the nature of the tangible causes; that many of these causes are physical or sensory and can be discovered on careful investigation; that this search must be instituted early in life because the mental development in normal children is so incredibly rapid that a lagging behind even for an inconsiderable period makes it difficult to catch up even after the cause of the lagging is removed—"Such is the mere life of vegetation the baby lives during the first two months; no grown person ever experienced such an expansion of life, such progress from power to power in that length;" [15] and that "if it is possible to perfect mankind, the means of doing it will be found in the medical sciences."

GONORRHEA TREATED WITH SUCCINIMIDE OF MERCURY ADMINISTERED INTRAMUSCULARLY.

(A PRELIMINARY REPORT.)

BY GEO. B. LAKE, M.D.,

CAPTAIN MEDICAL CORPS, U. S. ARMY.

THE writer has been very much interested in the treatment of gonorrhea for a number of years, this interest having been stimulated by the exceedingly gloomy prognosis given by most writers on the subject, and particularly by a case, formerly reported ("Neisser Bacterin in Chronic Gonorrheal Urethritis,"—Lake, *J. A. M. A.*, Vol. LIV, Feb. 19, 1910, page 611), in which he had an opportunity to exhaust his therapeutic armamentarium during thirteen months of treatment, with no perceptible effect on the course of the malady or the condition of the patient.

During the next two years trials were made of various remedies, logically or empirically suggested, such as diphtheria antitoxin and iodized lime, administered intramuscularly, and various other local and systemic medicaments, but no results worthy of mention were obtained.

During the winter of 1912-13 the writer was in charge of the venereal ward in the Military Hospital at Ft. Sheridan, Ill., and, despairing of finding any specific treatment for gonorrhea, endeavored to work out a routine ward treatment which would shorten the stay in hospital of these unfortunate patients, while giving them a reasonable prospect of a cure of their malady. There was no means of determining what the requirements for discharge had formerly been, but the average stay in hospital, in fifty cases, was found to have been 15.72 days per case.

The treatment described below was decided upon after various experiments, and resulted in reducing the average stay in hospital, in 32 cases, to 11.75 days per case (a saving of three days), with a standard for discharge of two consecutive days of entire freedom from urethral discharge. A number of these cases, however, showed gonococci for a long time after they left the hospital. This treatment and its results are given in detail because it was used in all the cases to be reported at this time, except where otherwise stated, in connection with the mercurial treatment.

One admission to the hospital the patients were all given a purge of 5 grains each of calomel and sodium bicarbonate, followed next morning by a large dose of Epsom salts, kept strictly in bed upon liquid diet, and ordered to inject a penis syringeful of a 2 per cent. solution of protargol after each urination and hold it for five minutes. As soon as the discharge was reduced to mere moisture (usually in four or five days) the patient was permitted to be up and was given light diet, and, in addition to the protargol injections, received two irrigations daily of a 1-3000 solution of potassium permanganate. When the urethral discharge had been entirely absent for two days the patients were discharged from the hospital, but were followed up to determine the time when the gonocci disappeared for two consecutive days. In the 21 cases where the occi did eventually disappear this time averaged 26.86 days. During this time daily irrigations of potassium permanganate solution were kept up.

This may not seem a very rosy report, but considering the fact that the discharge *did* become negative in 68.75 per cent. of the cases treated, it compares favorably with the results under other forms of routine treatment, and fairly well satisfied the writer for a time. The matter of a specific for gonorrhea was, however, kept in mind and various drugs studied as to their possibilities in this line.

Early in 1914, while stationed at Augur Barracks, Jolo, P. I., a soldier of the Hospital Corps reported that he had an obstinate case of chronic gonorrhea of which he was very anxious to be cured, and that he had heard a laboratory assistant from another hospital say that he had seen cases clear up after succinimide of mercury had been administered for other conditions.

Remembering the pronounced tonic and alterative properties of mercury, and the remarkable results of Wright's use of this drug in tuberculosis, together with the fact that many of the older writers held it in high esteem as a general systemic antiseptic, the writer decided to give it a trial in this case (see Case I). The results were so striking that the treatment was used in other cases, nineteen of which are now to be reported in detail.

This article is in the nature of a preliminary report, as other cases are now under treatment, and various modifications will be tired and reported upon at a later date.

Case I.—W. H. J., white soldier. Has had numerous attacks of gonorrhea, as well as chancroids and syphilis, for which latter he has received three intravenous injections of salvarsan. The present attack of gonorrhea has lasted for nine months, with a constant milky discharge, constantly positive for gonococci, although he has been assiduous in the use of irrigations of solution of potassium permanganate. On March 23, 1914, the discharge was examined and found to contain very many pus cells and gonococci in every field. On this day he received 40 mgm. of mercury succinimide, intramuscularly in the left buttock, at 10.00 A. M. In the afternoon he complained of slight headache and dizziness, but this passed off before night. On March 24 the discharge was about the same and still showed many pus cells, but only one cell was found containing gonococci, after examining many fields. On March 25 and 26 the discharge was much less and very few gonococci were found. March 27, very little discharge, no gonococci found. On this date a second injection of 40 mgm. of the mercury salt was given in the right buttock. March 28, patient had a metallic taste in the mouth and slight tenderness of the gums, but this cleared up in a day or two. Marach 28 to April 2, inclusive, mere moisture at meatus—negative for gonococci. April 23 no discharge for three weeks, except slight stickiness at meatus after he has had an erection. Negative for gonococci. June 5, no discharge, no gonococci. November 2, no discharge, no gonococci (smear from prostate). This man ate full diet and did full duty during the entire treatment. He continued his irrigations until March 30, since when no local treatment has been used.

Case II.—A. S., Filipino soldier. Patient had gonorrhea several months ago. At present has a free, purulent discharge from the urethra. March 14 to 29, inclusive, gonococci abundant. March 27, 40 mgm. of mercury succinimide given in buttock. March 29, discharge reduced to mere moisture; on 30th it stopped. April 3 and 4, negative for gonococci. On the evening of the 4th, five drops of a 2 per cent. solution of silver nitrate were instilled into the urethra. April 5, discharge moderate. Negative for gonococci. June 22, no discharge. No gonococci. November 2, no discharge, no gonococci (prostatic secretion).

Case III.—A. O., Filipino soldier. Denies venereal history. Has free, purulent discharge. March 30 to April 4, inclusive, gonococci abundant. April 3, received 40 mgm. of mercury succinimide in buttock. April 4, discharge mere moisture. (This continued until the 9th, and was probably due to phimosis, which was later relieved by circumcision.) April 6 to 12, inclusive, and 22, negative for gonococci. On April 13 he developed a suspicious papular eruption, which was diagnosed syphilis (his Wassermann proved to be double plus) and salvarsan was administered on April 20 and 30, with entire control of the symptoms. June 22. No discharge. No gonococci. September 16 and 27 and November 2, negative. (All prostatic.)

Case IV.—B., Moro soldier. Denies venereal history. Free purulent discharge and edema of the prepuce. April 1 to 12, inclusive, gonococci present every day. April 10, received 40 mgm. mercury succinimide in buttock. April 12, discharge mere moisture; dry on April 16. April 14, 17, and 18, negative for gonococci. June 26, no discharge; no gonococci. September 19 and November 2, negative. (Prostatic).

Case V.—A., Moro Soldier. Denies venereal history. Free, purulent discharge and acute epididymitis, right side. April 10 to 17, inclusive, discharge positive for gonococci. April 15 received 13 mgm. mercury succinimide. (The supply had run low) in the left buttock. April 16, developed fever, which went to 102.2° F. and subsided on the 19th, at which time there was little or no discharge and the epididymis was nearly normal. Discharge ceased entirely and epididymis normal on April 21. April 19 to 24, inclusive, gonococci negative. April 25, positive. April 26 to 30, inclusive, no gonococci present. May 29, patient returned to hospital with a free, milky discharge and slight pain and swelling in the right epididymis. He had been having very violent drill (wall scaling). At rest in bed on liquid diet his discharge ceased in 48 hours. It was negative for gonococci at all times, up to and including June 8. June 1, received 65 mgm. mercury succinimide in buttock. Temperature went to 100° on the 2nd, and

subsided next day. June 22, no discharge; no gonococci. June 30, September 19, and November 2, negative (prostatic).

Case VI.—C., Moro soldier. Denies venereal history. Moderate mucopurulent discharge. May 3 to 27, inclusive, discharge continuously positive for gonococci. May 3 and 7, received 40 mgm. of mercury succinimide in buttocks. May 26, received 65 mgm. of the mercury salt in right buttock. May 28 to 31, inclusive, discharge negative for gonococci. June 22, no discharge, no gonococci. September 19 and November 2, negative (prostatic).

Case VII.—A. O., Filipino soldier. Denies venereal history. Moderate mucopurulent discharge. May 12 to 18, inclusive, discharge positive for gonococci. May 15 received 40 mgm. of mercury succinimide in buttock. May 21, 22, and 23, discharge negative for gonococci. June 22, no discharge; no gonococci.

Case VIII.—A., Moro soldier. Denies venereal history. Moderate mucopurulent discharge. May 13 and 15, discharge positive for gonococci. May 15, received 40 mgm. of mercury succinimide in buttock. May 17, 19, and 20, discharge negative for gonococci. June 22, discharge positive for gonococci. Ordered into hospital again. June 23 and 24, still positive. June 24, received 78 mgm. of mercury succinimide in buttock. June 25, 26, and 27, negative for gonococci. September 14, 1914, readmitted with profuse, purulent discharge. (All signs of a fresh infection.) Placed on ward treatment. September 14 and 15, many gonococci in discharge. September 15, received 26 mgm. of mercury succinimide. September 16, one cell found with gonococci, after careful search. September 17 to 19, inclusive, negative for gonococci. All smears except the first were made from prostatic squeezings. September 26, negative for gonococci (prostatic). October 11, positive for gonococci. November 2, negative for gonococci (prostatic).

Case IX.—P., Moro soldier. Denies venereal history. Moderate purulent discharge. May 25 to 27, discharge positive for gonococci. May 26, received 65 mgm. of mercury succinimide in buttock. May 28, 29, and 30, discharge negative for gonococci. A moderate mercurial stomatitis developed on May 28, but cleared up in a few days. June 22, no discharge. No gonococci. August 11, September 27, and November 2, negative (prostatic).

Case X.—J. 2nd., Moro soldier. Denies venereal history. Profuse purulent discharge, for 6 days. June 3 and 4, discharge positive for gonococci. June 3, received 65 mgm. of mercury succinimide in buttock. June 5 to 10, inclusive, and 22, no discharge; no gonococci.

Case XI.—B., Moro constabulary. Says he has had gonorrhea twice this year (probably recurrences). At present has gonorrhea and multiple chancroids. June 4, received 65 mgm. of mercury succinimide in buttock. June 5, 6, and 7, discharge showed a few gonococci. June 8, 9, and 10, discharge mere moisture. Negative. June 21 and 22, discharge positive for gonococci. June 21, received 78 mgm. of mercury succinimide in buttock. June 23 to 28, inclusive, no discharge; no gonococci. This patient has been on full diet and without local treatment since June 16. July 8, 12, 14, and 19, negative for gonococci (prostatic).

Case XII.—S., Moro constabulary. Had gonorrhea in 1911. Moderate purulent discharge. June 21 and 22, positive for gonococci. June 21, received 78 mgm. mercury succinimide. June 23 to 28, inclusive, negative for gonococci. June 22, slight stomatitis, which cleared up in 3 days. June 24, swelling and tenderness at site of injection, cleared up in a few days. No treatment except the mercury was given.

Case XIII.—A. B., Filipino soldier. Denies venereal history. Slight moisture at meatus, and a mild epididymitis, right side. June 23 to 26, inclusive, negative for gonococci. June 24 to July 4, inclusive, positive for gonococci. June 28, received 78 mgm. of mercury succinimide. June 29, stomatitis, local pain and induration, temperature 100° F. All cleared up in a few days. July 5, received 40 mgm. mercury succinimide. July 5, 6, and 7, negative for gonococci.

Case XIV.—L. M., Filipino soldier. Had gonorrhea in April, 1914. Did not receive mercury treatment. Now has slight mucopurulent discharge. June 22 to July 4, inclusive, discharge positive for gonococci. June 28, received 78 mgm. of mercury succinimide. July 5, received 40 mgm. of mercury succinimide. July 5 to 9, inclusive, negative for gonococci. No other treatment was given with the mercury. A slight stomatitis appeared after the first dose. October 4, gonococci again found in discharge. Apparently a new infection. Case now under treatment.

Case XV.—O., Hindu civilian. Denies venereal history. Not taken into hospital. Leads a very unhygienic life and never carried out directions faithfully. Was treated from time to time by native and Chinese "doctors." Suffered with inflammation of both epididymides at different times. Was under treatment for 4 months in all, and received four injections of 78, 40,* 65,* and 90 mgm. of mercury succinimide, respectively, after which he always improved for a time and then relapsed. Still under treatment. This case is classed as an entire failure of the method.

Case XVI.—L. D. T., American civilian. Has had gonorrhea three times, last time two years ago. Not in hospital. Working entire time of treatment. First seen July 12, at which time there was no discharge, but meatus was red and moist and there was uneasiness in urethra. Secretion positive for gonococci. July 12, received 78 mgm. of mercury succinimide. July 16, negative for gonococci; no symptoms whatever; no discomfort from mercury. August 20, has had no symptoms since first day. November 3, no discharge, no gonococci (prostatic). Local treatment consisted of injections of argyrol solution.

Case XVII.—M., Moro soldier. Has had gonorrhea previously. Profuse purulent discharge. July 14 to 27, inclusive, positive for gonococci. July 15, received 78 mgm. of mercury succinimide. July 22, received 40 mgm. of mercury succinimide.* July 28 to 31, inclusive, negative for gonococci. Discharge ceased entirely on July 28.

Case XVIII.—L., Moro soldier. Denies venereal history. Moderate purulent discharge. This case is recorded as a failure. In hospital from July 16 to September 2, under various forms of treatment all the time. Received three injections of mercury, of 78, 40,* and 65* mgm. of mercury succinimide, respectively. Developed a right epididymitis and a cystitis while under treatment, and was transferred to the Department Hospital, Manila.

Case XIX.—Z. M., Filipino soldier. Had gonorrhea two years ago. Profuse purulent discharge. July 26 to 28, inclusive, positive for gonococci. July 27, received 78 mgm. of mercury succinimide.* July 29 to Aug. 1, inclusive, negative for gonococci. July 31, received 65 mgm. of mercury succinimide. November 10, no discharge, no gonococci (prostatic).

Case XX.—L. F., Filipino soldier. Denies venereal history. Moderate purulent discharge. August 8 to 12, inclusive, positive for gonococci. August 10, received 65 mgm. of mercury succinimide.* August 13 to 17, inclusive, negative for gonococci. August 18 to 25, inclusive, positive for gonococci. August 22, instilled 5 drops of 2 per cent. silver nitrate into urethra. August 29 to Sept. 2, inclusive, negative for gonococci. (Last 3 smears were from prostatic squeezings.) September 7, readmitted with profuse discharge and many gonococci. September 8 to 28, inclusive, positive for gonococci. September 11, received 78 mgm. of mercury succinimide. September 30 to October 2, inclusive, negative for gonococci. (Discharge varied greatly in quantity and character. Several specimens—including the last two—were prostatic.) October 9 and November 3, no discharge, no gonococci (prostatic).

Of the first eight cases in this series, seven received, in the first instances, doses of 40 mgm. of the mercury succinimide, and one had only 13 mgm.

Of these eight cases, seven became clear of gonococci quite promptly; one in two days, one in three days, three in four days, and two in six days; the other patient remained positive after two doses of 40 mgm. of the drug. One of the seven cases that cleared up (Case VIII) relasped (or was reinfected) after several weeks, but this man and the one who did not clear up on the smaller doses (Case (VI), both became negative within 48 hours after receiving doses of 78 and 65 mgm., respectively. Case VI has remained clear, but Case VIII relapsed again,

*All the doses marked with an asterisk were given with a preparation of mercury which had in some way deteriorated, being of a brown color and the tablets softened. It was all that was on hand at the time. It is not known how this would affect its action.

and again cleared up in a few days after the mercury.

Twelve cases received initial doses of 65 or 78 mgm. of the mercury salt, and of these, ten promptly became free from gonococci (five in 2 days, one in 4 days, 2 in 7 days, one in 13 days, and one in 19 days) while two showed no good effects from the drug whatever (Cases XV and XVIII).

Of the ten, three (Cases IX, XVI and XIX) have remained continuously clear up to date; one (Case X) was clear for three weeks and was then discharged the service; two relapsed in two or three weeks, received another injection of the mercury, in larger dosage, cleared up again and have remained clear (Cases XI and XX); two (Cases XIV and XVII) relapsed (or were reinfected) two and one-half and three months, respectively, after leaving the hospital, and are now under treatment; and two (Cases XII and XIII) could not be followed up.

Thus, in the 20 cases, we find that 13 (65 per cent.) became clear of gonococci in an average time of 6.7 days, and have remained clear for periods ranging from 3 weeks to 7 months. Two (Cases XIV and XVII) remained clear for several months and were then, in all probability, reinfected; this would raise the number to 15 (75 per cent.). It is possible that one or both of the two cases which could not be followed up remained clear also.

Of the remaining three cases, one (Case XVIII) pursued an untoward course without any assignable cause; one (Case XV) never pursued the treatment consistently, and was using all sorts of weird remedies, prescribed by native "medicine men," and one (Case VIII) seems, in my opinion, as likely to have been reinfected as to have relapsed.

At this point it may be well to state that among these people a recurrence after two or three weeks is very likely to be a reinfection, for they are exceedingly promiscuous and undisciplined in their sexual relations, and a man who has just left the hospital after an attack of gonorrhea is almost certain to spend his first night outside in the arms of a woman who is, in all probability, herself infected. Thus, if a case remains free from gonococci for several weeks, it is fairly safe to assume that the man is cured, while if the organisms do reappear after two or three weeks it is, at least an even chance that there has been an exposure and a reinfection.

From the foregoing it will be seen that the results in these 20 cases show 65 per cent. cured in an average time of less than one week; 15 per cent. probably cured and reinfected; 10 per cent. lost for purposes of record, and only 10 per cent. showing wholly unsatisfactory results.

Three cases (XII, XIII and XIV) had no local treatment at all. Two of these have not been followed up and the other relapsed, so, for the present, at least, it seems best to accompany the mercurial treatment with the old and accepted local and internal remedies.

The bacteriological work on the first twelve of these cases (in the other eight cases the work was done by the writer) has been done with exceptional care and thoroughness by Dr. Chas. H. Halliday, 1st Lieut. Medical Reserve Corps, U. S. Army, to whom I am indebted for most valuable assistance. In the most kindly spirit he has worked against me all through this series of cases, in the endeavor to prove the idea either right or wrong.

He visited the wards at all sorts of hours so as to catch the patients unprepared; he passed platinum loops up to the posterior urethra in all cases in taking specimens; he stained every specimen both with methylene blue and by Gram's method, making the preparations himself and using a slightly modified Gram stain, which gave very beautiful results, as follows: (1) Stained with aniline-gentian-violet solution for 30 seconds. (2) Washed in water. (3) Slide covered with Gram's iodine solution for 30 seconds. (4) Washed in water. (5) Washed in 95 per cent. alcohol until color ceased to come out of smear. (6) Washed in water. (7) Stained with Bismark brown for 30 seconds.

In examining the specimens he found that most of them showed a variety of bacterial flora, and, to ascertain whether or not this had anything to do with the course of the disease, he examined three healthy soldiers and found that they all presented the same conditions.

He noted an interesting point in several of the cases and reported it to me in a note regarding Case VIII, as follows: "There are bodies in this smear which, to me, present very interesting possibilities. On June 23 and 24 this case showed numerous gonococci by Gram's method; on June 25 it was found negative; after a careful examination, however, there were numerous Gram positive organisms found in the smear. On June 26 there are a few Gram positive cocci present, though the smear is negative for gonococci. Throughout the field there occur many oval bodies, varying in size from a coccus to 1/3 the size of a red blood cell. These bodies present the following appearance: The smaller ones are stained throughout their structure; as they increase in size the staining reaction becomes somewhat changed, the organism appears to be deeply stained about its margins, becoming paler as the center is approached, until, in the largest forms, the body is stained only at the edge, leaving a clear space within more than half the size of the body. Examination of the slide also presents very minute bodies, much smaller than a coccus, and deeply stained. While an opinion of any value should not and cannot be advanced simply on the staining reaction of an organism, it is worth while to remember that all bacteria make some effort at self-protection when being subjected to adverse conditions; also that those bacteria which form spores, at first become enlarged, their staining reaction changed, and in their last stage present a body entirely changed in shape and size."

This note opens up a field of study for bacteriologists who have an opportunity to observe any cases which may be treated by this method by other observers.

The technique of giving the injections is simple. The syringe must be all-glass, and it and the needles, which are better made of platinum, must be carefully sterilized by boiling. The desired dose of the mercury salt is dissolved in 1 or 1.5 c.c. of hot water. The site of injection (usually the buttock) is sterilized with tincture of iodine and the needle is plunged deeply into the muscular tissues, the fluid ejected and the needle withdrawn. The spot is then once more touched with iodine.

There is considerable pain for an hour or two after the injection, but in all of these cases this has passed away promptly (usually within 24 hours), leaving no bad effects. Two cases (V and XIII) had what appeared to be a reaction to the drug, as in them the temperature rose after all injections and subsided promptly without any treatment, leaving no unpleasant results. Several cases developed a mild stomatitis, which subsided in a few days.

It appears, from a study of these cases, that the earlier doses were too small to give certain results, and, at present, the writer is giving 65 mgm. or more of the mercury succinimide as an initial dose in every case, and may increase the dose still further. It is now believed, also, that a second, smaller dose (say 40 mgm.) should follow the first after from three to six days, especially if the gonococci do not disappear within that time.

Of course, no definite conclusions can be drawn from so few cases as those here reported, and they are submitted only with the hope that others may be induced to use this drug as outlined, and that their results may establish or disestablish its value in this class of cases.

The writer wishes to express his disappointment at the fact that the valuable article on the use of mercury succinimide, by Surgeon B. L. Wright, U. S. N., in the MEDICAL RECORD for July 11, did not reach his hands until after the cases here recorded were complete, and this paper largely written. In fact, the original paper, embodying the first twelve cases, was submitted for approval on June 29, 1914. The suggestions made in Dr. Wright's paper are, however, being carried out in some other cases now under treatment, and the results will be reported at a later date.

AUGUR BARRACKS, JOLO, SULU, P. I.

THE USE OF DECANTED BLOOD SERUM AFTER SEVERE HEMORRHAGE AND IN HEMOPHILIA.

REPORT OF TWO CASES.

BY ASPINWALL JUDD, M.D.,

NEW YORK.

ADJ. PROF. SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

IN reporting the following cases, it is my desire to emphasize the benefit that can sometimes be derived from the simple injection of decanted blood serum where other more scientific but more elaborate and more difficult measures are not available. In these days when the direct transfusion of blood in hemorrhage and in diseases of the blood is of such frequent report and the benefits derived of such undoubted value, of course, the choice of procedure is transfusion, but there are times when, as in the two cases to be reported, this cannot be accomplished. In such cases we sometimes overlook the fact that in a lesser degree we have at our command at once a simple, and at any rate, if not always efficient, a harmless means of assisting in restoring certain elements to the blood. No technique is required that is not available to the general practitioner. No harm can result from its use, or at least, no harm that is not inherent in the more difficult procedure of transfusion. Hemolysis is, of course, always somewhat of a danger unless the blood of donor and recipient is first tested, but as many transfusions are undertaken without this test and as few untoward effects have been reported, this could in emergency be dispensed with, especially if donor and recipient are closely related. In extreme hemorrhage in an adult, where a volume of blood is required, coincident intravenous infusion of normal saline solution with or without the addition of adrenalin in sufficient quantity to bring up the fluid content of blood, could be added; but in children even this is not required. It is truly remarkable to note the rapid gain in hemoglobin and in the number of red cells following this procedure. In the cases reported the final result is fully as good as in any case of transfusion that I have seen or done.

CASE I was a baby, aged fourteen months. Diagnosis: Fracture of skull, right parietal bone, with rupture of the middle meningeal artery. I saw her first on May 17, four days after the fracture, which occurred as a result of a fall from a bed. The child at this time had a temperature of 106°, pulse 140 and almost imperceptible; respiration, 46. In the right parietal region was a hematoma of enormous size. The blood had burrowed anteriorly and the cheek was also much enlarged and the right eye closed. The child was unconscious and had been so for some time.

The operation was simple, consisting of an incision over the mass, the cleaning out of the clot and trephining over the site of the fracture. When this was accomplished another blood clot of some size, which had burrowed in the membranes, was discovered, and the middle meningeal artery was found torn and still bleeding. This was tied, the clot was thoroughly evacuated, and the wound washed out with saline and closed without drainage. The child was pretty well exsanguinated, the hemaglobin about 40 per cent., and almost no blood pressure.

With a child of this age it was impossible to do transfusion successfully by the methods at this time in vogue, and even had the Lindermann method been at this time available, I doubt if we could have used it successfully. I, therefore, resorted to the method about to be described. On May 18, 20 c.c. of decanted serum, in the afternoon of the same day 20 c.c.; May 19, 40 c.c.; May 21, 40 c.c., and May 22, 60 c.c. of decanted blood serum, taken from the mother, was injected slowly into the losse tissue beneath the skin into the abdominal wall. There was practically no reaction. Recovery was uneventful, the wound healing by primary union. The little patient gained rapidly in weight. The color index of the blood rose to 70 per cent. within six weeks. The baby was a normal child.

It is not unusual in these cases, as in transfusion, to get a reaction, but except in cases of hemorrhage it is transitory and not to be regarded.

The technique used in securing the blood is quite simple. A donor as closely related as possible (as in transfusion) should be obtained. A healthy adult in early life is preferable. Mother or father or adult brother or sister is most desirable. Examination of hemoglobin and data as to the rapidity of clotting are next in order, but in case of necessity this can be determined sufficiently accurately by the simple method of pricking the finger with a needle. The test for hemolysis can be dispensed with. We must bear in mind that the proportion of blood to serum is roughly two to five. That is, in 100 c.c. of blood we will get about 40 c.c. of serum. Such an amount is taken from the cephalic or other prominent vein of the donor as will answer our need or such an amount as the donor can spare. In the case of my baby, 180 c.c. of serum represented 450 c.c. of blood obtained from the mother in two separate sittings. This is a somewhat exceptional amount, but the mother was an extremely healthy, full-blooded woman, the condition of the child was desperate, and the father was a weak, puny specimen. If a sufficient quantity of blood cannot be obtained from one donor, of course a second one can be used. No harm beyond a simple anemia, which quickly responded to treatment, resulted to the mother, and as the case history shows, the result to the child was very satisfactory. After drawing the blood from the vein into a clean, sterilized glass vessel it is preferably put in an incubator for a half hour, although this is not absolutely necessary provided

a temperature of blood heat is maintained. It is then placed upon ice or in a thoroughly cool place, protected by cotton from the air until the blood separates from the clot. From one to twelve hours is required. The serum is then decanted and kept in a cool place until needed. It can be kept for several days if upon ice. An ordinary glass or metal aspirating syringe answers the purpose of injecting admirably. In this instance thirty hours after the operation we made our first injection.

Case II.—A young man, nineteen years of age, with a tuberculous involvement of the head of the femur with destruction of the head, was presented to me. As the result of a previous operation, which was uncompleted on account of tremendous hemorrhage, a secondary infection had occurred. Upon admission to the hospital the patient was running a septic temperature ranging from 100° to 105°, accompanied by great prostration and intense pain. Even a simple drainage resulted in such considerable hemorrhage as to make any further procedure inadvisable. The boy gave a clear history of hemophilia.

Two efforts were made at transfusion, the donor being the father, a big, plethoric German weighing about 250 pounds, with hemoglobin of 100 per cent., but extreme rapidity of clotting in each instance prevented us getting any considerable quantity of blood into the boy's veins. I then resorted to the method already described, using a somewhat larger quantity of blood serum and injecting it all into the back and the abdomen in two sittings. Within forty-eight hours a test for bleeding showed a normal period of blood clotting.

The operation performed is of no special interest. A complete excision of the joint down to the tuberosity was accomplished with only normal hemorrhage, and although the wound was packed and drained, no secondary hemorrhage occurred at any time.

A rather remarkable feature in this case is that up to the present time, more than three years after the operation, there has been no recurrence of any tendency toward hemophilia. The boy's blood picture and clotting time is normal and his hemoglobin is more than 90 per cent. Murphy and others have reported the same interesting fact in cases of hemophilia, but so far as I can find this is the longest period that the blood picture has remained normal.

137 West Sixty-ninth Street.

FURTHER REMARKS ON THE RETENTION OF SALVARSAN.

By W. J. McGURN, M.D.,

BOSTON.

Failure of elimination after the intravenous administration of salvarsan, with its subsequent oxidization in the blood, is now generally accepted to be the causative factor in most cases of salvarsan fatality. The hypothesis advanced by Wechselmann, that the retention of salvarsan is dependent upon degenerative changes in the renal epithelium due to previous mercury administration, is not likely to become conclusive. In fact it is known that death has followed closely upon the intravenous injection of salvarsan and neosalvarsan in cases where mercury had not previously been given. This alone places emphasis upon our present inadequate knowledge of the toxicity of these agents and should suggest to every physician, interested in safe salvarsan therapy, the importance not only of a most careful technique, but also a searching inquiry into the physiological action of the drug, together with a study of its physical and chemical behavior, when preparing solutions for intravenous administration.

Before proceeding with the discussion I wish to present for consideration the opinon: *that the retention of salvarsan is due to the fact that the retained portion was not in chemical solution when introduced into the blood stream,* and to offer in evidence of the plausibility of this opinion the result of clinical observations which extend over a period of about three and one-half years.

Salvarsan as it reaches the physician is a yellowish powder, much of which, in the process of its manufacture, is physically reduced to very minute subdivisions, the size of individual granules being slightly smaller than that of the red blood corpuscle. When suspended in distilled water or 0.5 per cent. sodium chloride solution, these minute particles become gelatinous in character and may be present in great numbers without interfering with the transparency of the mixture, for it is only when a considerable number of these granules agglutinate that they become visible to the naked eye.

Whoever has had experience in the preparation of acid solutions of salvarsan is, of course, familiar with the adherent tenacity with which these gelatinous masses cling to glass, and with their persistent refusal of aqueous bondage. The extent to which these bodies avoid dissolution depends somewhat upon the temperature, and greatly upon the purity, of the water employed.

In the early days of intravenous salvarsan administration it was noticed that severe illness often followed when bacteria, *living or dead,* were present in the water used in preparation of the solution. The logical explanation of this is, that bacteria offer a powerful affinity for salvarsan and, when in contact with particles of that agent, they act as nuclei for microscopic masses of the drug, which after the most vigorous shaking, with or without glass beads, avoid aqueous solution; then, when carried into the general circulation, not being capable of rapid elimination, they act as reducing bodies to the formation of violent toxic agents capable of producing degenerative changes in the parenchymae, with resultant illness and death.

Ehrlich in his advices on the mixing of salvarsan made use of the terms "acid solution," "alkaline solution," also "neutral suspension" and gave specific directions for the preparation of each. These directions, of necessity, have been more or less modified by most physicians who have made an attempt to follow them, so that every solution of salvarsan represents to some extent the personal equation of the individual clinician. Some of our American authors, when speaking of the neutralization of salvarsan, have shown a fondness for the term "accurate titration" but frankly admit they have no means other than simple inspection by which to determine the accuracy of the reaction.

Much that is misleading has transpired in regard to the preparation of "neutral solutions" and "faintly alkaline solutions" of salvarsan, for in the light of investigation, salvarsan fails to fulfil the requirements of the term solution, except when distinctly acid or alkaline in reaction. When 0.6 gram of salvarsan is dissolved in 40 c.c. of fresh distilled water, a transparent acid mixture is obtained, but until filtered the constant presence of insoluble bodies should forbid its acceptance as constituting a chemical solution.

According to advices emanating from the George Speyer House, it would appear that the addition of 24 drops of a 15 per cent. solution of chemically pure sodium hydrate is capable of converting 0.6 gram of salvarsan in "acid solution" to a solution alkaline in reaction. While it is true that a somewhat transparent mixture is usually obtained after

the addition of from 23 to 26 drops of the sodium hydrate solution, it is also worthy of note that the mixture becomes much clearer after the further addition of one or more drops of the hydrate, the transparency increasing with each drop until the liquid begins to sparkle on shaking. It is not until then, however, that a high percentage of the salvarsan is actually in chemical solution. If at this point the mixture is passed through a dense layer of "chemically pure" compressed cotton, a distinct precipitate is shown which is found to be soluble only by the further addition of sodium hydrate. That these insoluble bodies are great in number and of appreciable size is proven by filtering through a porcelain tube, of sufficient porosity to permit the passage of the smaller types of micro-organisms, but at the same time prove impervious to bodies one-third the size of the red blood corpuscle. Such a filter invariably reveals the presence of much that is not in solution and furnishes a filtrate that is free from contamination, so far as can be determined, by its passage through the finer laboratory tubes often spoken of as "germ-proof" filters.

To Mr. Gowdy, of the Boston Filter Company, I am indebted for his prolonged efforts which finally resulted in the production of a filter exactly suited to verify the hypothesis advanced by me in the *Boston Medical and Surgical Journal*, November 14, 1912, and have made possible the present amplification of my former article on the retention of salvarsan.

From the beginning of salvarsan therapy great importance has been placed on the necessity of a clear, transparent solution for intravenous use, and much stress laid upon the dangers of the drug when wholly or partially suspended. No doubt all have tried to fulfil Ehrlich's dictates in this respect, but if an experience with more than four hundred specimens of these agents (salvarsan and neosalvarsan) is worthy of opinion, I would express the belief that 5 to 10 per cent. of all salvarsan and 1 to 3 per cent. of all neosalvarsan that has been given intravenously, entered the veins while suspended from their supposed solutions. It is true that I have never seen a salvarsan solution filtered through porcelain that did not leave a distinct residue, the amount of which depended greatly upon the temperature and purity of the distilled water used, and more particularly upon the quantity of sodic hydrate employed.

When the porcelain filter is used and it is seen that a residue is accumulating upon its surface, much of the precipitate can be rapidly dissolved by the addition of one to three drops more of the 15 per cent. sodium hydrate solution. The total amount found necessary for the complete chemical solution of 0.6 gram salvarsan is seldom less than 26 and usually not more than 32 drops. "Complete chemical solution" is intended to mean all that the ampul contained which was capable of aqueous solution, for there is unquestionable proof that in every instance insoluble bodies remain after the filter has been flushed with gallons of both distilled water and 0.5 per cent. sodium chloride solution even when an excess of sodic hydrate was added. Proof that these bodies are too large to penetrate the substance of the porcelain is furnished by gently brushing its surface with pumice or carborundum, which completely removes all trace of the precipitate.

Spasm of vein and the moderate burning sensation, experienced by many patients, which extends from the point of entrance in the vein to the axilla and often as far as the cordium, should be regarded as evidence of a poor solution, since these phenomena never occur when a porcelain filter is clinically employed.

Of the two cases of anuria which I saw in December, 1911, each followed an intravenous injection of 0.6 gram salvarsan (filtered through linen only) where an attempt was made by "accurate titration" to secure a "faintly alkaline" solution. The anuria, which extended over a period of thirty-six hours, was accompanied by severe headache, pain in the back, nausea, some diarrhea and slight hemorrhage from mucous membranes, and was followed in each case by an hematuria that continued for about one week. Chemical and microscopic analysis of the urine at the end of one month did not reveal the presence of any pathological condition. Since then this man and wife have each received three intravenous injections of 0.6 gram salvarsan without subsequent reaction of any kind. Prior to the first administration neither had taken mercury but following the second and third doses each was given a liberal amount of the protiodide by mouth.

Some of the facts acquired as a result of these observations are:

1. Salvarsan cannot be produced in pure chemical solution until it has passed a filter equal to that of a porcelain tube.

2. From 26 to 32 drops (standardized to one minim each) of a 15 per cent. solution of sodium hydrate are necessary to the production or 0.6 gram salvarsan in alkaline solution.

3. The dilution of an alkaline solution of salvarsan with sodium chloride solution reduces the percentage of its alkalinity and often causes a sudden precipitation of the drug, with a faint leuco-opalescence appearing throughout the liquid.

4. Vigorous shaking with distilled water free from microorganisms at a temperature of at least 110° F. is important as the first step in the mixing of salvarsan.

A question which may be justly propounded is: What effect does this higher percentage of alkalinity have on the action of the drug as a spirochetacide? While at present no fixed or definite answer can be given, the clinical results together with a limited number of serological reactions would indicate a proportional increase of efficiency. Of all patients treated by me with both salvarsan and neosalvarsan, 90 per cent. in number elect salvarsan as the one from which they derived the greater benefit, and it is to this opinion that the writer is inclined.

In conclusion I wish to sanction the opinion expressed by Dr. Clarence Martin of St. Louis that "the last word on salvarsan is far from having been written," and to reaffirm my belief that salvarsan retention means salvarsan fatality; also, that retained salvarsan with its resultant hemorrhagic encephalitis or acute degenerative nephritis would not have occurred had it not been for the presence, in the solution, of insoluble salvarsan bodies which could not have passed a porcelain tube; and finally, that when scientific methods are universally employed in the intravenous administration of salvarsan and neosalvarsan, the last word on "the pathogenesis of salvarsan fatalities" will have been written and the "retention of salvarsan" forgotten.

It is to be regretted that many of the afflicted are holding aloof from salvarsan today through

fear engendered by the not infrequent disastrous results reported through the public press; for it is highly probable that, when due respect is given its *avoidable dangers*, salvarsan is one of the safest and most efficient drugs ever employed as an heroic therapeutic agent.

A NEW INSTRUMENT FOR SCARIFYING IN THE VON PIRQUET CUTANEOUS TUBERCULIN TEST.

By W. H. LUCKETT, M.D., F.A.C.S.,

NEW YORK.

ROGERS has shown that the mortality of all children up to ten years of age who have a von Pirquet reaction is much higher than in children who do not so react; this conclusion being based on the subsequent history of sixty-nine children giving a positive von Pirquet reaction in the Massachusetts General Hospital. They had been out of the hospital on an average of two and one-third years. The importance of the test as to its prognostic value is thus illustrated and this also gives force to Miller and Woodruff's contention to keep every case giving the reaction "under careful observation." Frazer makes an earnest plea for its further trial and for standardization of the test.

The popularity of the test is undeservedly on the wane. The reaction has fallen into disrepute in certain quarters, with the general practitioner in particular. This is based upon faulty technique

and a consequential misinterpretation of the reaction. After a continuous and wide experience extending over a period of six years with the same scarifier and a standard solution, I am of the opinion that it is a most valuable asset in determining the probable early presence of otherwise undetectable deposits, and in helping to differentiate certain surgical lesions. Particularly must I refute the oft repeated assertion that the test is so commonly positive in adults as to cast doubt on its value. Personal equation enters strongly in determining the test. The indiscriminate use of broken matches, toothpicks, needles, and scalpels as scarifiers is to be condemned. A standard scarifier and a standard solution alone should be employed.

In February, 1909, I had Tiemann make a scarifier after the model of a jeweler's cup-shaped swivel-headed watch screw-driver with longitudinal corrugations. Shortly after this, believing that the indiscriminate dipping of the scarifier into a vial of tuberculin was not conducive to thorough asepis, I had old tuberculin put up in capillary tubes containing each two minims. Each tube is for one test. These tubes are now carried in stock together with full printed directions.

The essence of the test is a careful attention in detail to the technique. The wide variation in opinion of the efficacy of the test is due in a large measure to a lack of appreciation of this technique together with a misinterpretation of the reaction.

To operate, grasp the forearm of the patient from behind with the left hand retracting the skin posteriorly in such a manner as to make it tense over the anterior aspect. This is absolutely necessary in order to always and regularly control the depth of the scarification. The scarifier is held in the right hand with the tip of the index finger in the cupped head and revolved in one direction between the thumb and middle finger, making ever so gentle pressure the while, only the veriest superficial scarification is made, three in number, at least one and a half inches apart. They should be identical, perfectly round and two mm. in diameter. Neither blood nor serum should ever be drawn. The capillary tube of tuberculin is broken and one drop is placed on each end scarification. The middle is the control. The tuberculin is then partially dried by a current of air from an empty atomizer and a sterile dressing is applied.

The accompanying cut is two-thirds the actual size.

18 WEST EIGHTY-SEVENTH STREET.

Medicolegal Notes.

Mortality Tables as Evidence.—The effect of mortality tables as evidence, if any, is a question for the jury. Proof that the person whose expectancy of life is under consideration conforms to the standards of health and vigor adopted in compiling mortality tables is not essential to their admissibility. Evidence of disease or of ill health or of hazardous employment may impair or destroy the probative effect of tables of expectancy of life, but it does not make them inadmissible.—Broz v. Omaha M. & G. Hospital Assn, Nebraska Supreme Court, 148 N. W. 575.

Medical Associations—By-Laws as to Medical Defense—Duty to Defend—Demand.—Action was brought against a medical association by one of its members, to recover the expenses paid in defending a malpractice suit, the defense of which the plaintiff claimed the association was obligated under its laws to conduct. One of the purposes of the association was "to guard and foster the material interests of its members and to protect them against imposition." It adopted by-laws relating to "Medical Defense." Section 1 provided that members should be entitled, on the conditions after specified, to receive, without charge, legal advice and court service, etc., when accused of malpractice. Section 2 made it the duty of the council to investigate all claims of malpractice against its members, and to adjust them when possible, "and if in their judgment an adjustment is impossible, or the claim is unjust, or the damage sought is excessive," to tender aid, etc. Section 3 provided for an annual report of all such suits or threatened suits. Section 4 prescribed conditions, the only one relevant to the present case being the fifth, "The association will assume the defense in a suit for malpractice against a member only when the cause for the alleged malpractice occurred subsequent to the date on which the member joined the association." These by-laws went into force April 1, 1910.

Liability of Private Hospitals for Negligence of Nurses.—A patient was admitted to a hospital conducted for private gain while suffering from a temporary mental disorder, which impelled him intermittently to leave his bed and act irrationally. In the night, while without an attendant, he gained access to a sickroom where poison was kept. Some of this he swallowed and died. In an action against the hospital it was held that a hospital conducted for private gain is liable to a patient for the negligence of nurses, while acting within the scope of their employment. Where a patient in a hospital is treated by a physician who does not manage or control the hospital, he is not liable for the negligence of hospital nurses or internes, if he had no connection with any negligent act. A patient is generally admitted to a hospital conducted for private gain under an implied obligation that he shall receive such reasonable care and attention for his safety as his mental and physical condition, if known, may require. Whether the hospital was negligent, in the present case, in allowing the patient access to the sickroom was held to be a question for the jury. Judgment given for the plaintiff was affirmed.—Broz v. Omaha Maternity & G. Hospital Assn., Nebraska Supreme Court, 148 N. W. 575.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, April 17, 1915.

NATIONAL QUARANTINE.

THE anomaly of the local (State or city) control of quarantine has almost disappeared from this country, and if the efforts now being made to effect the transfer of the New York station to the United States Public Health Service are successful, the passing of this antiquated and irrational system will positively be assured. Since 1888 the quarantine functions at sixty-six ports of the United States have been transferred to national control. The Boston quarantine is the latest to make the change, and there now remain but three ports where the Public Health Service is not in full control, viz., New York, Baltimore, and Galveston. The question of transfer is being actively considered at all three of these places and there is no question that if New York leads the way the other two will follow promptly.

There is every reason why the National Government should control the quarantine service of the entire country, for the function of quarantine is as much a national affair as the inspection of immigrants; indeed, it is impossible to dissociate the two. At this port, when an attempt is made to keep the two separate, one under State, the other under national control, although the State quarantine officers make the first inspection no steerage passenger can land until he has passed through the immigrant station at Ellis Island where he is again examined by the surgeons of the Public Health Service. The State quarantine is superfluous and the double examination is a waste of labor and an altogether unnecessary expense to the State of New York.

The Merchants' Association of this city has expressed itself as strongly in favor of the transfer of the quarantine at this port to the National Government and has requested the Governor to take the necessary steps in that direction. The Public Health Committee of the New York Academy of Medicine has passed resolutions in favor of this change; these resolutions have been endorsed by a number of organizations and individuals in this city and elsewhere in the State, and they will undoubtedly be adopted by the meeting which is to be held at the Academy of Medicine on April 20 to discuss the situation.

Typhus and typhoid fevers, cholera, and smallpox are prevailing to a frightful extent in several of the belligerent countries of Europe, and as soon as the war ends and free communication with this country is reestablished we shall be in the greatest danger of the importation of those diseases in the bodies of the sick and especially of seemingly healthy carriers. To avert such a calamity, this harbor, which is the chief port of entry for immigrants who later will scatter to every State in the Union, should be guarded by the specially trained and expert sanitarians of the United States Public Health Service. If such an irruption of disease appears imminent, the National Government will almost certainly take possession of quarantine here, as it has the right to do in an emergency; but how much better that its officers should already be in control and thoroughly familiar with the physical conditions of the station before putting it to the test of repelling the fierce onslaughts of these infections.

THE EXUDATIVE DIATHESIS.

IT is now ten years since Czerny outlined sharply the condition which he called the exudative diathesis, and during this time it has grown to have a considerable place in pediatric literature. From the first it was considered to be evidence of disturbed metabolism, but the results of investigations have been conflicting, and the exact nature of the disturbance and its cause have remained unsolved problems. Niemann has carried out very complete metabolism studies upon three children suffering with this condition and has drawn therefrom certain interesting conclusions.* He selected nursing infants in whom the eczematous manifestations were not such as to lead by their irritability, to increase in muscular activity. In all of his cases he was able to demonstrate an increase in the production of heat and of carbon dioxide over the normal, and he considers such increase as characteristic of the condition. The children naturally divide themselves into two groups, one obviously thin and undernourished, the other apparently fat but of the "pasty" type. The weight curves were subject to rather marked and rapidly changing variations which were much more noticeable in the "pasty" type, and Niemann advances the theory, which is supported by his evidence, that the fat children were fat in a different way from normally fat babies. In these patients the increased weight was due almost wholly to the retention of a large quantity of water. There was no disturbance in the absorptive power of the intestines and a certain number of the patients developed symptoms while still at the breast.

In application of these findings to the treatment Niemann was led to avoid the addition of carbohydrates to the food since under such conditions the storing of water is rendered easy. Also the feeding of increased amounts of protein was not thought advisable in view of the specific dynamic action of protein in increasing a metabolism already abnormally high. He therefore treated

*Der Stoffwechsel bei exsudativer Diathese. Von Priv.-Doz. Dr. Albert Niemann, Assistenten an der Universitäts-Kinderklinik in Berlin. Price M. 2.80. Bonn: A. Marcus & E. Webers Verlag, 1914

his patients by increasing the fat content of the food, not by the addition of cream, for that would increase also the sugar and the carbohydrates, but by the use of washed butter. His results were very striking. Within a few days from the beginning of his butter feeding the skin manifestations began to clear up and in a short period of time the patients were apparently well. The "lability" of their metabolism persisted for variable lengths of time, but he was able to control it by this method and regularly obtained satisfactory results.

In any consideration of a work of this kind it must, of course, be remembered that our metabolism studies are carried on for the most part in such a manner that we are able to see only just beneath the surface, and all deductions must be made with the realization that the introduction of improved methods may disprove them completely. Nevertheless it is by such studies that our information is increased, and with increase in knowledge comes increase in power.

VOLKMANN'S CONTRACTURE AND FRACTURES AROUND THE ELBOW JOINT.

This unfortunate condition may follow embolism, thrombosis, crushing injuries, too long application of the Esmarch bandage or other interference with the arterial blood supply or the venous return; but the majority of such cases are seen following fractures, and it is this type only which concerns us just now. After fractures of the elbow or forearm, typical cases of Volkmann's ischemic paralysis and contracture of the flexor muscles of the forearm and hand are occasionally seen. It is usually found that the causative factor has been compression of the vessels by the maintenance of too sharp flexion at the elbow or there has been too great constriction at some point in the forearm by adhesive plaster strips or bandages holding splints in place. In most cases constriction of the vessels has existed for several hours, but cases have also been reported in which constriction did not last over half an hour and still Volkmann's paralysis resulted. As Volkmann himself pointed out, the lesion is primary in the muscles and not in the nerves, as is shown by the fact that paralysis occurs and contracture begins practically simultaneously, while with primary nerve lesions there is first a paralysis and, if it occurs at all, contracture is a late manifestation. Occasionally there is a combination of ischemic paralysis of the Volkmann type and an associated nerve lesion leading to subsequent degenerative changes in the muscles supplied by that nerve. The ischemia results in rapid degeneration of the individual muscle cells, infiltration, and ultimate replacement fibrosis. Contracture begins almost immediately, and in an incredibly short time the muscles present a board-like hardness together with marked shortening, the fingers are flexed at the interphalangeal joints, and later the wrist becomes partially or completely flexed. Until extension at the wrist is interfered with the fingers can be extended painlessly when the wrist is flexed, thus showing that there is no inflammation in the tendon sheaths but merely a contracture of the muscles, pulling the tendons up in their unaltered sheaths. Pain may or may not be noted when Volkmann's paralysis is imminent, but there is always swelling; hence a patient with a fracture dressing should be instructed to see the surgeon at once if undue swelling of the hand occurs after the application of splints to the upper arm, elbow, forearm, or wrist. Children are the victims of this unfortunate paralysis more often than adults and the parents should always be impressed with the absolute necessity of bringing the child to the surgeon without delay if undue swelling occurs.

While Volkmann's contracture following fracture is almost always the result of too tight dressings there are occasional exceptions, and a very interesting case of this unusual type is reported by Guyot, whose article is abstracted in the *Archives de Médecine des Enfants*, January, 1915. A six-year-old girl fell about five feet, striking the right elbow, which immediately became painful and began to swell. After a "bone-setter" had treated the region by massage and mobilization for a month the child was taken to a hospital. Examination then showed considerable limitation of motion at the elbow joint, while the child naturally held the forearm flexed on the arm at an angle of about 120 degrees; the wrist was half flexed on the forearm; the fingers were in a position of semiflexion, and with attempts to extend the wrist the fingers became still more sharply flexed; the tendency to pronation of the wrist was marked; pulsation in the radial artery could not be felt, and there was an abnormal reddish discoloration of the skin of the peripheral part of the injured member. Examination showed that there had been a supracondyloid fracture of the humerus with anterior and upward displacement of the lower fragment. Union had taken place with the lower fragment in that bad position and in such a way as to cause pressure upon the median nerve and brachial artery.

Here, then, was a typical case of Volkmann's contracture following fracture, but in which no retentive apparatus of any kind had been used; yet the contracture was undoubtedly the result of faulty treatment, for a competent surgeon would have recognized the nature of the injury and malposition of the fragment which was causing interference with the blood supply and would at least have seen to it that pressure was relieved. The deformity and other symptoms following supracondyloid fracture of the humerus or separation of the lower humeral epiphysis are so typical that accurate diagnosis and failure to secure at least approximate reduction are hard to explain now that expert radiography is almost universally available.

Fractures, especially those around the elbow joint, are a fruitful source of malpractice suits. In some of these fractures a certain amount of functional impairment is unavoidable, since reduction and retention in a position of anatomical perfection are often impossible—a fact recognized not only by the profession but also by the average jury. Volkmann's contracture, however, in cases where

the blood supply is not seriously interfered with at the time of the original injury, is, with possibly very rare exceptions, plainly due to one of three things: (1) incomplete reduction; (2) the faulty application of dressings (and this includes the failure to provide for the inevitable swelling that takes place in the traumatized region); (3) the failure of the patient to follow instructions and return at once for readjustment of dressings at the first sign of pressure symptoms. The aphorism "Eternal vigilance is the price of safety" is eminently applicable in connection with fractures around the elbow joint, not only that we may give the patient the best possible result and prevent unnecessary complications, but in order to protect ourselves from the danger of legal entanglements, with possible financial loss and certain damage to professional reputation.

The Probable Prevalence of Venereal Disease.

It is manifestly a matter of extreme difficulty to estimate correctly the prevalence of venereal disease in any community, owing to the absence of authentic records of definite value. Dr. Charles G. Banks, writing in Public Health Reports, February 26, 1915, suggests as a basis of estimate, as probably the nearest approach to a normal comparison with the general population, the class known as seamen. After pointing out that seamen are generally supposed, and with some truth, to be proverbially careless with regard both to drink and to sexual intercourse, he goes on to say that it would also be imagined that venereal disease is rife among them. However, statistics of the Public Health Service show that but one case in five among seamen is of venereal origin and if the professional and popular conception is different from the facts we may be prepared to admit the now obvious conclusion that the same class of disease is not prevalent among the general public to the extent claimed by some. Arguing then from the standpoint that the sailor is the extreme probability, numerically speaking, of the gonorrheic and syphilitic in our problem, the high water mark, indeed, in the possibilities, Banks is of the opinion that the prevalence of syphilis has been considerably exaggerated. He considers from an analysis of the situation that the actual number of persons acquiring venereal disease in the United States is less than 3 per cent. annually, although it would be an impossibility without a complete census to ascertain the number of persons actually infected with venereal disease at any single date. As is pointed out, the real interest centers practically in facing the problem for the future, not in estimating the exact damages of the past. It is really a campaign for prevention, and we can start out by saying that we have to meet with nearly two and a half million cases of venereal diseases annually treated in the United States, about one person in every forty.

Hypochlorite Treatment of Water Supplies.

The hypochlorite treatment of water supplies has met with a considerable degree of success, and is being employed largely throughout the United States and Canada, and in other parts of the civilized world. In Public Health Reports, February 26, 1915, H. A. Whittaker, assistant director, Division of Sanitation, Minnesota State Board of Health, describes portable emergency hypochlorite plants constructed in 1910 by the board of health to be kept in readiness for immediate transportation to localities within the State where water supplies were suspected or known to be contaminated. The writer announces that these plants have rendered great service, as their constant readiness and portability have made it possible to reach practically any public water supply in the State, install a plant, and treat the water within a period of twenty-four hours after notice has been received by the division in charge of the work. He further states that the plant and equipment described by him make it possible for a trained worker to enter the field equipped to handle in an emergency the problems met with in treating a polluted water supply.

News of the Week.

For Belgium Relief.—The following is the report of the treasurer of the committee of American physicians for the aid of the Belgian profession for the week ending April 10, 1915:

The Cooke County Medical Society, Gainesville, Texas	$15.00
The Sedgwick County Medical Society, Wichita, Kan.	25.00
Dr. Carl B. Davis, Chicago, Ill.	10.00
Dr. R. C. Dorr, Batesville, Ark.	5.00
Anonymous, "J," New York, N. Y.	5.00
Dr. George Leonard Schadt, Springfield, Mass.	5.00
Dr. Mark T. Goldstine, Chicago, Ill.	10.00
Dr. Lomax Gwathmey, Norfolk, Va.	25.00
Dr. J. C. Chipman, Sterling, Colo.	5.00
Miss Grace Hutchison, Canton, N. Y.	2.25
Dr. Brooke M. Anspach, Philadelphia, Pa.	5.00
Dr. J. B. Haskins, Chattanooga, Tenn.	15.00
Dr. Fred W. Phifer, Wheatland, Wyo.	5.00
Dr. Henry P. Brown, Jr., Philadelphia, Pa.	10.00
Dr. Floyd W. McRae, Atlanta, Ga.	10.00
Dr. William L. Rodman, Philadelphia, Pa.	25.00
Anonymous, "F," St. Johnsbury, Vt.	10.00
Dr. Joseph P. Murphy, Brooklyn, N. Y.	5.00
Dr. Rudolph Matas, New Orleans, La.	25.00
Dr. Neal N. Wood, First Lieut. M. C., U. S. A., Schofield Barracks, Hawaii	5.00
Cumberland County Medical Society, Bridgeton, N. J.	10.00
Gonzales County Medical Society, Gonzales, Texas	10.00
Receipts for the week ending April 10th	$242.25
Previously reported receipts	5,896.50
Total receipts	$6,138.75
Previously reported disbursements:	
1,625 standard boxes of food at $2.20	$3,575.00
1,009 standard boxes of food at $2.30	2,320.70
Disbursements for the week ending April 10:	
105 standard boxes of food at $2.30	241.50
Total disbursements	6,137.20
Balance	$1.55

One box of surgical instruments sent to The American Commission for Relief in Belgium, through *Surgery, Gynecology and Obstetrics*, without name of donor and without a list of contents.

Protest of Mayors against the Hinman Anti-Health Bills.—The New York State Conference of Mayors, held in Middletown last week, registered a strong protest against the passage of the amendments, introduced in the Legislature by Assemblyman Hinman, crippling the health laws of the State. In a letter sent to all the members of the Legislature, the Conference, which represents the officials of all of the fifty-four cities in the State, sincerely regrets the effort to emasculate the Public Health law, and to cripple its administration. The Conference considers that the reduction in the number of sanitary districts and cutting down the Supervisors' salaries would make it difficult to get efficient service. Making the divisions of the Health Department permissive instead of mandatory is strongly deprecated, as is the taking from the Health Council the power to prescribe qualifications for places on the Department staff. But the protest is especially strong in its condemna-

tion of the bill depriving the Health Council of the power to enact sanitary regulations

Return of American Hospital Physicians.—Dr. Samuel L. Ledbetter, Jr., member of the staff of Lakeside Hospital, Cleveland, who has been at work in the American Ambulance Hospital at Neuilly, Paris, returned last week on the *Philadelphia* of the American Line.

The Mortality of the War.—According to the *Avanti*, a Roman newspaper, the total loss of men by all nations at war during the first eight months numbers 5,950,000. The amount of money spent during the fist six months is estimated at $8,400,000,000.

Death Rate Increased.—The report of the New York City Health Department for the week ending April 3 states that there were 1,831 deaths which was 219 more than in the corresponding week of 1914. The most potent factor of this increased mortality, the report states, was the prevalence of influenza in a more virulent form than has happened in some years, with a corresponding increase in the deaths from acute respiratory diseases and organic diseases of the heart. There were 407 deaths from acute bronchitis, bronchopneumonia and lobar pneumonia, this number being in excess by 143 of the number of deaths reported from these causes in 1914. In addition to this the organic heart diseases showed an increase of forty-two deaths.

Ravages of Typhus in Serbia.—Another American Red Cross surgeon has fallen a victim of typhus fever in Serbia, Dr. Ernest P. Magruder of Washington. The first of the band to die was Dr. James F. Donnelly of this city. Of the six American surgeons and twelve nurses who went in the Red Cross units to Serbia, the only one who has escaped the disease is Dr. Butler, the head of the second unit. When Dr. Edward Ryan, who was in charge of the first American Red Cross unit in Serbia, was stricken, Dr. Magruder was put in charge of the work.

Rockefeller Institute for the Study of Animal Diseases.—The signing by Gov. Fielder of the bill recently passed by the New Jersey Legislature, permitting experimentation on animals under the supervision of the Board of Health, has made possible the establishment of an institute for scientific research in animal diseases. The buildings will be erected near Princeton and the institution will be under the direction of Dr. Theobald Smith.

Surgeon General Gorgas has been offered by the trustees of the Rockefeller Foundation the position of advisor in problems of public health. If he accepts he will be obliged to retire from the Army, though not necessarily to resign unless he is sent to Serbia, in which, being belligerent territory, he would probably be unable to work even in the saving of life while a retired army officer.

The Louisiana State Board of Medical Examiners announces that, beginning with June 1, 1915, candidates for licensure must show evidence that they have completed one full year, at an approved college or university, of work in the branches of biology, physics, chemistry, and in one modern language.

Death of Prof. Friedrich Loeffler.—Announcement was made in Berlin on April 9, of the death of Friedrich Loeffler, professor of hygiene in the medical faculty of the University of Griefswald, Prussia, and director of the Hygienic Institute, and perhaps best known as one of the discoverers of the *Bacillus diphtheriæ* or Klebs-Loeffler bacillus. Prof. Loeffler was also the discoverer of the glanders bacillus, the bacillus of mouse typhoid, and other pathogenic organisms, and was the author of many important treatises on medical and hygienic subjects. He was in his sixty-third year.

For Quarantine Transfer.—A meeting will be held at the New York Academy of Medicine on Tuesday evening, April 20, at 8.30 o'clock, for the purpose of advocating the transfer of the quarantine station at this port to the control of the United States Public Health Service. Addresses will be made by Mr. Henry James, Jr., on "The Present Health Conditions in Europe and Their Relation to This Country in the Coming Months"; Dr. William C. Woodward on "The Menace of Inadequate Quarantine and What an Efficient Quarantine Means to the Entire Country," and ex-President William Howard Taft on "The Relation of the National Government to Quarantine and Other Public Health Agencies."

Typhus Vaccine.—At a meeting of the New York Pathological Society on Wednesday of this week, it was announced that a vaccine against typhus fever had been prepared by Dr. Harry Plotz, the discoverer of the typhus bacillus (*B. typhi exanthematici*), and that Dr. Hans Zinsser and others who recently left New York to fight the typhus epidemic in Serbia had been inoculated with the vaccine before sailing.

The End of the Coroner System.—On April 14 Gov. Whitman signed the Stoddard bill abolishing the office of Coroner in New York City and providing for the appointment by Mayor Mitchel of a chief medical examiner, who is to name assistants to do the work now performed by Coroners. The new law goes into effect when the terms of the present coroners expire. Eleven coroners and the same number of coroners' physicians are affected by this change.

A New Physicians' Building.—It is reported that the physicians have leased the old Calumet Club building at Fifth avenue and Twenty-ninth street and purpose dividing the house with offices for physicians.

Charitable Bequests.—By the will of the late Admiral C. Drennen, of Easton, Pa., bequests are made as follows: to the hospital of the University of Pennsylvania, $5,000, for the endowment of a bed or beds for children, and $5,000, for the endowment of a bed for adults; to the Easton Hospital, $5,000, for the endowment of a bed.

The Warren Triennial Prize, which was founded by the late Dr. J. Mason Warren in memory of his father, is awarded every three years for the best dissertation considered worthy of a premium, on some subject in Physiology, Surgery, or Pathological Anatomy; the arbitrators being the physicians and surgeons of the Massachusetts General Hospital. The prize, amounting to $500, will be awarded in 1916. Dissertations must be in English, French or German, and must be typewritten and suitably bound, so as to be easily handled. Work that has been published previously will not be considered in competition. The name of the writer must be enclosed in a sealed envelope, on which must be written a motto corresponding with one on the accompanying dissertation. Dissertations will be received until April 14, 1916, by Dr. Frederic A. Washburn, Resident Physician, Massachusetts General Hospital, Boston.

Obituary Notes.—Dr. William H. Randle of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1878, a member of the Medical Society of the State of Pennsylvania and the Philadelphia County Medical Society, and an expert on yellow fever, having served as a member of the Yellow Fever Commission appointed by President Hayes in 1878, died at the Jewish Hospital, Philadelphia, with which he had been connected for many years, on April 2, following a mastoid operation, aged 64 years.

Dr. Nancy M. Miller of New York, a graduate of the New York Medical College and Hospital for Women in 1867, and well known as a writer on hygiene and health reform, died at her home on March 15, aged 84 years.

Dr. David Polk Juett of Blandville, Ky., a graduate of the Jefferson Medical College, Philadelphia, in 1857, died at his home after a long illness, from cancer of the stomach, on March 8, aged 79 years.

Dr. Alfred Mason Amadon, formerly of Boston, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1897 and a member of the American Medical Association, the Massachusetts Medical Society, the American Otological Society, and the New England Otological and Laryngological Society, died at Saranac Lake, N. Y., from tuberculosis, after a long illness, on March 7, aged 47 years.

Dr. Gregory Arvide Martin of Franklin, Mass., a graduate of the University of Vermont, College of Medicine, Burlington, in 1879, for twenty years chairman of the Board of Health of Franklin, died at his home, after a long illness, from Bright's disease, on March 9, aged 72 years.

Dr. Joseph Bascom Griswold of Grand Rapids, Mich., a graduate of Rush Medical College, Chicago, in 1868, a veteran of the Civil War and senior vice commander of the G. A. R., and a member and former president of the Michigan State and Kent County Medical Societies, died at his home after a long illness on March 9, aged 72 years.

Dr. Thomas E. R. Miller, formerly of Frederick, Md., died at Lewistown on March 2 at the age of 71 years. He was graduated from Miami Medical College in the class of 1866. During the Civil War he served in the hospitals of the Eighth Army Corps. He was at one time Pension Examiner, at another time a member of the Maryland Legislature, and for three years County Health Officer.

Dr. John Lincoln Bromley died at Philadelphia of heart disease on March 4 at the age of 46 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1891. He was ophthalmologist to the Episcopal Hospital and to St. Timothy's Hospital.

Dr. Annie W. Stauffer died at Philadelphia on March 3 at the age of 70 years. She was graduated from the Eclectic Medical College of New York City in the class of 1881.

Dr. Jules M. Rosenbloom died at Philadelphia on March 8 at the age of 35 years as the result of an opoeration for the relief of abdominal disease. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1905.

Dr. John C. Cotton, formerly of Meadville, Pa., died at Philadelphia on March 10 at the age of 86 years, as the result of an apoplectic stroke. He was graduated from the Cleveland University of Medicine and Surgery in the class of 1853. He was a volunteer surgeon at the battlefield of Gettysburg.

Dr. David F. Swisher of Darby, Pa., died at Jefferson Hospital at Philadelphia on March 1 as a result of pneumonia at the age of 47 years. He was graduated from Jefferson Medical College in the class of 1892.

Dr. Abram C. Treichler died on March 2 at Elizabethown, Pa., at the age of 71 years. He was graduated from Jefferson Medical College of Philadelphia in the class of 1871. He was physician to the Masonic Home at Elizabethtown. He was a member of the Lane County Medical Society and the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. Frank W. Flower of Carthage, Mo., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1876, at one time physician of Jasper County, and a member and former president of the Missouri Homeopathic Medical Society, died at his home after a long illness on March 7, aged 77 years.

Dr. Ethelbert H. Black of Rossburg, O., a graduate of the Curtis Physio-Medical Institute, Marion, Ind., in 1883, and a member of the Ohio State Medical Association, and the Darke County Medical Society, died at his home on March 9, aged 55 years.

Dr. Theodore Gaillard Croft of Aiken, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1875, a member and former presdent of the South Carolina Medical Association, and a member of the American Medical Association, and the Aiken County Medical Society, died on March 10, at the age of 69 years.

Dr. Isaac R. Phillips died at Philadelphia on March 11 as a result of pneumonia. He was a graduate of Jefferson Medical College of Philadelphia.

Dr. Smith Armor died at Columbia, Pa., on March 14 at the age of 91 years. He was graduated from the Homeopathic Medical College of Pennsylvania in the class of 1851.

Correspondence.

ARTIFICIAL GASTRIC JUICE IN GANGRENE.

To the Editor of the Medical Record:

Sir:—Referring to your editorial comment in the issue of March 13, on the treatment of gangrenous wounds with artificial gastric juice, I would say that I have used this method occasionally for about twenty years. As it is rather far-fetched to include such practice in gastroenterology, my experience has not been very large and has included only minor cases, as of felon, foul wounds of the hand, carbuncles, chronic ulcers with crusts, etc. I have used solutions of pepsin and hydrochloric acid and also solutions of vegetable digestants, mostly commercial papains. Like Freund, whom you quote, I have used hydrogen peroxide freely and think that it is fair to ascribe a good deal of the action to it. However, in carbuncles notably, a true digestant action on the core is manifest. It is scarcely necessary to state that when a clean granulating surface is obtained, ordinary dressings should be substituted, although there does not seem to be any practical danger of digesting living tissues, with any reasonable degree of caution. Usually, on the principle that one cannot spoil bad eggs, antisepsis and even asepsis may be neglected in the preliminary digestive treatment, though, of course, care should be taken not to introduce virulent bacteria by carelessness. A local anesthetic may be employed but is often unnecessary.

Buffalo, N. Y. A. L. Benedict, M.D.

A WARNING.

To the Editor of the Medical Record:

Sir:—A man has recently presented himself in Butler, Pa., as George H. Gray, Pathologist, State Board of Health, New York. He has left Butler, leaving some obligations behind him. This Department has never had anyone of this name in its employ, and I beg to suggest that you will make some mention of this matter in the Medical Record so that others may be warned against him.

Linsly R. Williams, M.D.,
Deputy Commissioner of Health.

State Department of Health,
Albany, N. Y.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RADIOTHERAPY—INFANT LIFE PROTECTION—WAR NOTES.

London, March 25, 1915.

Radium has of late demanded so much attention that the report of the London Radium Institute comes opportunely before the profession. This is the third annual report and during the year sixty-seven patients have been treated fully, and of these only two are reported as not being at all the better for it. There were, however, twenty-two which are stated definitely to have been improved. One case which applied was not treated at all. Even such a result, if that were all, might be called encouraging for cases so generally pronounced hopeless, for the Institute requires a medical recommendation as a condition of admission. Moreover, except rodent ulcer, no malignant case is accepted unless it is certified to be inoperable or unless the patient absolutely refuses to submit to operation. It seems a correct proceeding in an institute established chiefly for the purpose of determining the value and position of radium in therapeutics to exclude rodent ulcer, as that disease is more generally acknowledged to be largely amenable to the remedy.

But how about the forty-one cases not accounted for in the foregoing figures? They are reported as "apparently cured," and that is as much as may be properly stated in the present state of our knowledge. The medical superintendent interprets the term as representing a condition in which all trace of the original lesion has disappeared and the patient is free from any indication of it as far as careful examination can discover. He classes as "improved" cases, resulting in marked benefit either by retarding the progress of the disease, decreasing the size of the growth, healing ulceration, arresting hemorrhage and discharge, or relieving subjective symptoms such as tenderness, pain, itching, dyspnea, dysphagia, etc.

Radium can be used in the form of solution of its salts, or the emanations and applications, or glass or metal tubes of it are sold, as are also screens for filtering the rays, so to say. Three kinds of rays are distinguished by the names of the three first letters of the Greek alphabet.. Alpha rays rapidly lose their activity and are completely interrupted or absorbed by a very thin screen (0.01 mm. of aluminum). Beta rays are more penetrating, and those working with radium recognize two varieties "soft" and "hard." Gamma rays are extremely penetrating and should only be used by those experienced with radium.

Exposures to the emanations may be made for only a minute or two for slight or superficial effects, or may be prolonged for any time between that and a day or even more, according to the purpose of the application. A quarter, half, or an hour has been found useful against warts, nevus, ulcers, etc. The screening in these cases need not exceed 0.002 mm. aluminum. To destroy tissues twelve hours may be required, say, for rodent ulcer, epithelioma, lupus vulgaris, etc. These exposures are usually divided over two or three days, say, three hours at a time and no screening is used, or if any only 0.1 mm. of lead. Deep-seated malignant growths have been treated by exposures of twenty to one hundred hours. The reaction caused varies very much according to the apparatus and screening employed, the time of exposure, the nature of the tissue, its extent and condition. Personal idiosyncracy may also add to the difficulties of the medical attendant. The reaction appears, as a rule, in the second week and four degrees may be observed: (1) Simple erythema; (2) erythema succeeded by desquamation; (3) vesication with superficial ulceration; (4) deep ulceration, sometimes accompanied by the production of an eschar. Sometimes the reaction appears earlier, at other times later. It has been seen on the third day; on the other hand it has been delayed for four weeks.

A morning and evening clinic is held daily at the Institute, where 6,453 applications are reported to have been made during the last year. Of the persons sixty-seven, as mentioned above, were treated to a conclusion. Carcinoma furnished more cases than any other disease and the breast the organ most frequently attacked. The majority of the cases were recurrent, largely due, no doubt, to the policy of not admitting operable cases, except such as absolutely refused amputation. Of the cases of mammary cancer eight died, seventeen showed no improvement, but forty were decidedly improved and one was apparently cured. The repetition of these results is permissible as a preface to the statistics of the three years of the Institute's work combined. It appears that 224 cases have been treated in the three years, 32 of which died during that period, 27 gave up the treatment, 114 were considered to be improved, 47 were not improved, but 4 were apparently cured.

Of other diseases uterine cancer gave encouraging results; 27 cases with 1 apparent cure, 17 improved, 7 not, and 2 deaths. Of 6 cases of cancer of the bladder 2 showed remarkable improvement. Of rodent ulcer 65 cases were treated, 41 being reported as apparently cured, 23 improved, and 2 not better; 4 cases are reported at length, on the nose, scalp, cheek, and temple, respectively. Of lymphadenoma there were four cases, all improved, and it is stated that in this disease the striking feature is the rapidity of the diminution in size of the affected glands, the effect being often perceptible to the patients themselves within a week of the first exposure. Fourteen cases of adenoma of the thyroid who refused operation were treated, all being improved. Of arthritis deformans there were 168 cases, of which 91 were said to be improved, as many perhaps as could be expected in this extremely intractable disease. Numerous patients have also undergone "prophylactic irradiation," that is treatment with the hope of preventing or delaying recurrence after operations. The majority of these we are told had suffered from extensive and rapidly progressing malignant disease,

and the operators had warned them that it would probably return in a few months. It is thought cases may be most suitable for trial in which it has been found impossible to carry operation well beyond the diseased area.

These remarks on the working of the Radium Institute, though more lengthy than I usually give to a subject, afford but a feeble expression of the great value of this report of its third year. Anyone thinking of devoting attention to radiology in relation to therapeutics would do well to commence by mastering this voluminous report, which is to be obtained by medical men from the superintendent, Mr. A. E. Pinch, F.R.C.S., Riding House street, London, West.

The Royal Sanitary Institute had a conference on Saturday when infant life protection occupied most of the discussion. Dr. Brindley, Medical Health Officer for Derby, said public money had too long been spent at the wrong end, providing hospitals and other aids for the old instead of preserving life at the beginning. Health reformers were beginning to realize this. Colonel Kenwood, professor of hygiene at the University, urged that new energy and special services were called for to compensate for the tremendous wastage now occurring.

The war is still the absorbing topic with every section of the public.

In common conversation the Red Cross, the ambulance work, frost-bite, the casualties, the roll of honor are expressions continually heard, and the entrance of a doctor gives rise to a number of questions, more or less puzzling. Among medical men themselves military surgery, the mortality in various circumstances and the honors list are prominent subjects. The high compliment paid to the Royal Army Medical Corps by Lord Kitchener in his speech in the House of Lords has been fully appreciated. But in every medical chat on such matters the subject of typhoid is sure to intrude and demand the chief attention.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

NEW HOSPITAL AT CATTABATO—TUBERCULOUS LEPERS IN SAN LAZARO—EVIL EFFECT OF THE HARRISON ANTINARCOTIC BILL IN THE PHILIPPINES.

MANILA, February 10, 1915.

ARRANGEMENTS are being made to build a new hospital at Cattabato, to replace the one now in use, which was inherited from the army when Cattabato was abandoned as a military station. The present hospital is in bad condition. A preliminary appropriation of 20,000 pesos has been made toward the hospital, which will be built of native hard woods and have a capacity of fifty patients. The present hospital, which has been in operation for about a year, treated 749 cases in the first eight months, besides conducting a large outpatient service. The institution is proving very popular among the Moros of the Cattabato Valley, who are now resorting to it in large numbers. Moro cooks are now in charge of the preparation of food for the patients and this has removed the last objection, as the Moros, being Mohammedans, were afraid lest they lose their religion through unwittingly eating food in the preparation of which the flesh or fat of pigs had entered.

A separate building for lepers suffering from tuberculosis is planned for San Lazaro Hospital, if the recommendation of the leper committee is carried out and funds are found to be available. A good many cases of leprosy are found to have this dual infection—though quite recently several of the investigators here have announced their belief that the nodules so commonly found in the lungs of lepers after death are leprous rather than tuberculous.

Radical changes of the Philippine opium law will be effected by the antinarcotic law enacted by the Congress of the United States, and the extent and importance of these changes is now understood to engross the attention of the internal revenue, bureau of health, constabulary, attorney-general, and others. The bill was introduced by Governor-General Harrison, when a member of Congress, was passed on December 17 last, and copies of the act have just been received here. The antinarcotic act was made especially applicable to the Philippine Islands and other possessions and goes into effect on March 1, 1915. It provides for a special tax on all persons preparing, handling, or administering such drugs. The penal provisions of the act of Congress are generally much less severe than those obtaining under the local law, which has been in force about ten years and which is now superseded; and this is what gives particular concern to the officers of the local government, who fear that the effect will be disastrous in materially decreasing the protection against opium now afforded the people of the Philippine Islands. Under the old law the Chief of Constabulary had the enforcement of the law under his charge and possessed the power to compromise cases, which was often used as a warning and prevented repeated offenses. Under the new bill prosecution through the courts is the only resort. The antinarcotic bill was extended to the Philippines against the advice of the insular authorities, and an effort will now be made to induce Congress to repeal the Philippine proviso, which upsets all legislation relative to the opium traffic now existent in these islands. The latter has worked extremely well. The use of opium has steadily decreased, until it is now an almost negligible factor in health work. The few users are largely Chinese, who have been long addicted to opium or learned its use outside the islands. Under the law, an opium habitué is arrested and sent to Bilibid Prison for cure, which is brought about by ultimate total withdrawal of the drug. Conditions in the islands are in marked contrast to those in the neighboring island of Borneo, for example, where the chief profit of the British North Borneo Company is derived from the monopoly and sale of opium. There anyone can buy as much opium as desired, and as little as even seven cents, American money, will buy sufficient for a debauch. As a result, practically the entire Chinese population are said to be opium habitués, and certainly most of the Chinese and many of the Malays of British Borneo show marked effects of drug use. To deliberately impair the economic efficiency of a whole people seems a short-sighted policy from an economic standpoint, yet the North Borneo Company seems quite willing to do this for the sake of the immediate profits secured by promoting this most destructive vice.

Salt Fever in Infants.—G. Jörgensen confirms the observations of Samelson, Bendix, and Bergmann that the febrile reaction following the hypodermic injection of physiological salt solution in infants is avoided by the use of freshly distilled water in the preparation of the solution.—*Monatsschrift für Kinderheilkunde.*

Progress of Medical Science.

6. Some Nervous Affections in Which Massage Deserves More Frequent Use. J. W. Courtney.

4. The Menace of Syphilis to the Public. — J. H. Blaisdell states that the amount of syphilis in Massachusetts today is absolutely unknown. Figures from communities where the disease is reportable show it to be one of the two most prevalent infectious diseases. Every syphilitic case definitely exposes many innocent, clean living people to the disease. Sixty cases of fresh syphilis exposed 134 by coitus, 442 by family or boarding-house life, and 651 by occupational association—1,227 people in all. At present no organized effort is being made to round up the source of every case. Out of the sixty sources of this series only two were brought under medical care. These sixty cases infected at least five others, but no effort was made to trace out infections in over five hundred equally good possibilities. Left to themselves, patients make little effort to follow up even the most elementary treatment. Twenty-eight per cent. of the patients entering the clinic with active symptoms of syphilis never return for treatment. Seventy per cent. made less than five visits,—a number insufficient in most cases to relieve the presenting symptoms for which they entered. Aftr the first few months the syphilitic patients as a whole average only 25 per cent. of the visits required for minimum efficient treatment.

5. Scar Tension on Ulnar Nerve.—F. J. Cotton describes an affection of the ulnar nerve at the elbow, due to the intermittent tension produced by elbow motion on a nerve held rigidly fixed by a deep scar. The mechanism is purely fixation of the nerve by scar tissue, at the turn of the elbow, where it lies in the epitrochlear groove, or in the inch next below this point. Given a nerve so fixed, it must necessarily happen that flexion of the elbow must pull upon it, and ordinary use of the arm must give intermittent traction on the nerve trunk. The result may be in some measure a paresis in the muscles supplied by the nerve, sometimes with marked atrophy in the muscles of the hand, but more particularly the damage expresses itself in pain; pain radiating from the elbow down to the last two fingers, with numbness to touch in this region; a numbness not usually serious in itself, but important as an indication of real trouble. Pain and a partial paresis of the intrinsic muscles of the hand, expressed in weakness and clumsiness in executing the finer movements of the fingers, are the factors which principally form the list of complaints from the patient. Relief of this condition is surgical. Just as in the cases of intermittent nerve-pressure symptoms from recurrent luxation of the nerve at the elbow,—so here also, the only remedy is removal of the nerve to a more favorable site; one can relieve symptoms by dissecting out the nerve, carrying it forward, and imbedding it in loose fat and muscle.

2. Growth and Overgrowth.—P. G. Woolley notes that growth depends upon (1) the ability to grow (*i. e.* a certain type of unstable constitution); (2) the stimulus to grow (*i. e.* the action of a force which increases, temporarily, at least, the instability); (3) a sufficient food supply. The phenomenon of overgrowth is one which is recognized in very many forms which vary according to nomenclature from regeneration to tumors. It is seen in healing of wounds; in exuberant graulation tissue; in the gravid uterus; in the heart under varying conditions; in the hollow viscera whose activities are modified by the presence of stenoses; in the bloodvessels in conditions of high arterial pressure; in the skeletal muscles under the influence of exercise; in glandular organs when a part of the functional tissue is damaged; and in certain other organs, which, while they appear unlike, are parts of correlated systems, and so correlated that an absence of one member of the system produces increased activity on the part of the other members. It is seen in corns and calluses, in the fibroses, in the benign and malignant tumors. It is customary to speak of work overgrowth, adaptive overgrowth, compensatory overgrowth, irritative overgrowth, nutritional overgrowth, inflammatory hyperplasia, and neoplastic growth. The only difference between these lies in the sort of stimulus which brings about the cellular reactions. In the cases of work, adaptive, compensatory, and vicarious overgrowth, the stimuli belong in the realm to which one may apply the term "physiological." In the cases of irritative, inflammatory, or neoplastic growth, the stimuli belong in the category to which one may apply the term "pathological."

3. Subpectoral Abscess.—D. Riesman states that the constitutional symptoms of subpectoral abscess from the very beginning are out of proportion to the local manifestations. This is due to the fact that the streptococcus is the causative organism and that the free lymph circulation of the thorax permits of easy dissemination of the infection. In the treatment of subpectoral abscess the question arises whether it is better to wait for definite localization of the pus or to make an incision as soon as the diagnosis is established.

9. Functional Intestinal Stasis. — W. C. K. Berlin concludes that unhygienic oral and nasal cavities, errors of diet, together with idiosyncrasies for different foods (fats and burnt greases, yolks of eggs, etc.) are actual or predisposing causes of localized functional intestinal stasis. 2. Infections such as nephritis, bronchitis, empyema, tuberculosis, etc., apparently are directly traceable to this localized functional stasis. 3. Localized functional stasis must be remedied in order to make other treatment efficient and recovery possible. 4. Operative obliterations of a dilated caput cecum coli is justifiable for the reduction of a localized functional stasis when it occurs in this locality, and when other measures fail.

1. **The Cerebrospinal Fluid.** — C. H. Frazier points out that the original conception of the cerebrospinal fluid as a transudate has long been discarded. That the choroid plexus is a gland with an external secretion has been shown by the morphological studies of Pettit and Girard, by the similarity between the choroid plexus and the lachrymal gland as noted by Mott, and by the intra vitam staining methods of Goldmann. The impermeability of the choroid plexus to toxic substances injected into the circulation is further evidence in favor of the secretory theory. The author refers to the artificial production of hydrocephalus, and to the increased rate of flow of cerebrospinal fluid following the injection of extract of choroid. The cerebrospinal fluid has a dual origin; the greater part comes from the choroid plexus; but some is derived from the perivascular system of the nervous tissues. Possibly the two different parts have separate chemical and physiological properties. The functions of the cerebrospinal fluid are as follows: It is a mechanical water-bed protecting the brain and spinal cord against shock and injury; it equalizes and distributes pressure throughout the intracranial and intraspinal cavities; it serves a compensatory purpose in filling up dead spaces in cases of atrophy or congenital defects of the brain; it protects the nervous system against infection; it serves as a medium of exchange between the capillaries and nerve cells, and it distributes the active principle of the pituitary to the tissues of the central nervous system. The experiments of the author in conjunction with Peet have shown that whenever the rate of flow of cerebrospinal fluid is disturbed it is always accelerated and not diminished and coincident with the increased flow there is a fall in blood pressure. These results follow the injection of extracts of spleen, kidney, pancreas, and liver, and are attributed to the sudden dilatation of the cerebral sinuses forcing out fluid which had accumulated in the ventricles and subarachnoid space and to the stimulation of the choroid glands. Brain extract produces this stimulation irrespective of the amount of fall in blood pressure. Thyroid extract has a specific inhibitory effect on the action of the choroid plexus. Diiodotyrosin, a synthetic product identical with a substance found in the thyroid, has the same effect, although to a less marked degree. Ligation of the common carotid has no effect on the secretion of the cerebrospinal fluid. The absorption of the cerebrospinal fluid occurs principally by way of the venous channels, and it may rapidly meet unusual demands as when large quantities of salt solution are injected into the subarachnoid space. In serous meningitis the relief of increased intracranial pressure is effected more readily by a temporal decompression than by lumbar puncture. Increased intracranial tension in tumors is the result of a secondary hydrocephalus. It has now become possible to differentiate types of hydrocephalus; for example, an obstructive or a non-obstructive type. Of a given amount of phenolsulphonephthalein injected into the ventricles, 60 per cent. should be recovered in the urine in two hours. The use of thyroid extract is suggested in the treatment of suitable cases of hydrocephalus, on the basis of the inhibitory action of thyroid extract upon the secretion of the cerebrospinal fluid.

4. **The Preparation of Diabetic Patients for Operation.**—T. Addis believes that the estimation of the degree of impairment of the power of the body to oxidize fatty acids is of prime importance in deciding whether or not operation is advisable in any particular case; but the amount of acetone bodies (fatty acids) excreted does not give a reliable indication of the degree of danger, because, although that amount may be small, the reserve power of the body to deal with these substances may be very slight, so that there may be a sudden failure under the special strain induced by operation, with the result that diabetic coma ensues. What is needed is a functional test of the fatty acid oxidizing power. A method is outlined whereby, with very simple methods, the amount of acetone bodies or of ammonia under certain fixed conditions is compared with the quantity found under circumstances which call for a marked increase in the catabolism of fatty acids. The fear, excitement, and undernourishment of the patient, which frequently accompany operation, brings about a call for the utilization of the food stored in the body. This food consists of glyogen and fat, but the most easily available is glycogen, and there will be no very extensive breaking down of fat into fatty acids until the glyogen stores of the body are largely depleted. Even in cases in which the utilization of sugar is very defective, glyogen will diminish the amount of fat required in such emergencies. One aim of treatment should therefore be to bring about a storage of glyogen in the body before operation. The best means yet devised to this end is the oatmeal treatment introduced by von Noorden. The inability of the kidneys to excrete large amounts of fatty acids is a factor in the production of diabetic coma. The giving of alkali helps the kidneys in this work. Before operation, therefore, it is important to give alkali until the urine becomes alkaline, and to maintain if possible this alkaline reaction after operation. Neither success in inducing a storage of glycogen in the body before operation, nor in keeping the urine alkaline is an absolute barrier against diabetic coma. They are only palliative measures. All those circumstances which unite together to produce shock are factors which act as exciting causes of the condition known as diabetic coma. It is possible to mitigate the action of these agencies by the application of the principles of "anoci association."

7. **Rupture of Extensor Longus Pollicis.**—J. Ramsay Hunt states that extensor paralysis of the end phalanx of the thumb is a very rare affection. It results from rupture of the tendon of the extensor pollicis longus as it emerges from beneath the posterior annular ligament of the wrist. Trauma and a variety of occupations have been found to be the cause of this accident, all of which have tended to induce low-grade inflammatory and degenerative changes in the tendon, which predisposes to spontaneous rupture. Drummers are especially liable to this affection; hence the term "drummer's palsy." If evidences of union do not occur after a brief period of fixation of the part, function can be restored only by a tendon operation. The term "drummer's palsy" is a poor one and is misleading, for the reason that the lesion is not neural, and therefore not a true paralysis, nor is the condition one which is confined solely to drummers. Therefore, if this term is used, it should be with the understanding that the affection is one of the tendon and not of the nerve.

1. **The New Psychiatry.**—W. H. B. Stoddart in the second of the Morison Lectures discusses the sphere and the technique of psychoanalysis, which he finds applicable in the treatment of the neuroses, including neurasthenia, the anxiety neurosis, and some forms of hypochondriasis; the psychoneuroses, including hysteria, the compulsion neurosis, obsessions, and morbid fears; and the psychoses, including maniacal depressive insanity, dementia præcox, and paranoia. In the case of manic-depressive insanity no attempt should be made to analyze the patient during the course of one of his attacks. A partial analysis serving to lay bare the most obvious of the patient's repressed complexes is often sufficient to effect a permanent recovery, whereas anything like a complete Freudian analysis often does harm. Most of the cases of dementia præcox are too inaccessible mentally. The most favorable cases are those of katatonia. The psychoneuroses comprise the cases in which psychoanalytic treatment is eminently satisfactory. It is the duty of every physician who contemplates using the method either to be psychoanalyzed or to psychoanalyze himself so that he shall not read his own complexes into his patient.

3. **Rupture of Heart in a Child.**—J. Anderson reports a case of this condition in a girl aged five years, who had been apparently well previous to her sudden death. The lesion which had given rise to the rupture was of remarkable character; a hematoma, one-quarter inch in diameter, had formed in the wall of the left ventricle and septum. Its cavity was filled with blood clot and its walls were ragged and granular. At its lower aspect it had ruptured externally into the pericardium, and a large probe could easily be passed through the aperture, which was situated one-half inch from the base of the ventricle. The thinned inner wall communicated with the interior of the ventricle by a large and irregular aperture, which was continuous with an extensive rupture across the inner portion of the posterior wall of the chamber. The torn area almost encircled the ventricle, and reached as far as a point immediately beneath the position of the left auricular appendix. The laceration occupied a fair depth of the muscle, and the wall of the ventricle, when viewed by transmitted light, was quite translucent. The right ventricular wall was intact. The valves were of normal size and their curtains were healthy. Examination of the coronary vessels showed a stenosis of the lumen of both arteries, and the descending branch of the left coronary artery was obliterated at the seat of the rupture and could not be traced beyond it. The interpretation which was placed on the case was that the child was the subject of an abnormal development of the coronary arteries. The vessels were unusually narrow, and further, the lumen was encroached upon in places by the areas of thickening in the inner coat due evidently to a syphilitic endarteritis. The hematoma in the septum was more than likely the result of the thrombosis in the descending branch of the left coronary artery, and represented really a dissecting aneurysm of the heart wall; and the case is comparable with that described by Lazarus-Barlow, which, however, occurred in a man of advanced life. Another important factor in the case was inherited syphilis.

2. **Rôle of the Meningococcus in Meningitis.**—E. C. Hort, C. E. Lakin, and T. H. C. Benians advance the thesis that in cerebrospinal fever the meningococcus might prove to be a late noninfective phase in the life history of a minute organism not yet discovered, which is only infective in its earlier stages—that is to say, it is only in these early stages that it causes the disease. If this be so, the early infective phase might prove to differ widely, morphologically, culturally, and biochemically, from a late noninfective meningococcal phase. The basis for this theory was the fact that Hort and Ingram had already described a minute pleomorphic organism in typhus fever, and had produced experimental evidence, not yet completed, which suggested that this minute organism was in its earliest phases the primary infective agent in that disease, while the late phases were noninfective.

6. **Treatment of Painful Frostbite.** — W. C. Davis states that the problem of how best to treat painful frostbitten feet is one which doubtless has caused those in charge of military wards some anxiety. The best remedy the author has found to be cocain, 8 grains; olive oil, 4 drams, and lime water, 4 drams. A small quantity is rubbed into the feet twice daily, special attention being given to the toes; the feet are massaged with it for a few minutes, and afterward wrapped up in cotton wool. It is an improvement to add 1 ounce of liquid paraffin to 4 ounces of above preparation, as by this addition it is prevented from oxidizing so quickly, and also from drying up so rapidly, and makes it less liable to rancidity. When the oil dries on the feet, the following dusted on is an excellent powder: Camphor, 35 grains, and zinc oxide and powdered starch, of each ½ ounce.

7. **Pathometric Equations.**—Sir Ronald Ross contributes a new development of his studies on pathometry, *i.e.* the mathematical study of epidemiology. In these studies he followed the *a priori* method; in other words, he assumed a knowledge of the fundamental laws governing the time-to-time variations of disease in a population of living creatures; formed the corresponding difference and differential equations, and then sought by solving these to ascertain the more remote laws which should govern the variations if his assumptions were correct. The author's work was concerned chiefly with insect-borne diseases; but he gave brief but not quite complete integrated equations on the general theme, these equations being obtained on the supposition that the total population remains constant during the considered period of time. A year ago, however, he was able to remove this restriction by integrating the original differential equations even when the population varies, and he has now found a simplification which enables one to state the equations in forms which are easy to analyze and which will be understood by any one who has some knowledge of the calculus. Thus put, they give an elegant (though tentative) mathematical theory both of epidemic and endemic communicable diseases.

March 1, 1915.

War Aphorisms of a Dermatologist.—Unna discusses the single furuncle, furunculosis, and axillary abscess. In treating a furuncle the surgeon notices the direction of the hairs of the affected part and pulls up a broad fold of skin with the left hand, so that the furuncle is at the summit, and compresses it softly until a blood-

less area appears. In the center of this is a cylinder of cocci which surrounds the hair follicle and constitutes the future core of the boil. An attempt is made to puncture this cylinder with a hot needle, such as the finest paquelin. This enters in the direction of the hairs. Great heat is not necessary, as a common needle heated in a flame will answer. If this maneuver is properly done the cocci and their toxins are destroyed, and tension and pain at once disappear. Not until this moment does the operator release his hold on the fold of skin. If the attempt has failed it must be repeated. This procedure is superior throughout to the crucial incision. On the other hand, if there are a number of furuncles—a parent lesion having apparently propagated others—the surgeon should not think of an internal cause and treatment based thereon (unless of course he has to do with a diabetic); he may indeed, however, in civil practice, give yeast or calcium sulphide inwardly. On the field the individual boils should be cauterized as already described, but something must be superadded to attack the process as a whole and arrest the spread. The author recommends warmly a paste made of ichthyol and kaolin. But as neither of these may be present in the available hospital supplies, chalk may replace kaolin, and sulphur plus zinc oxide ichthyol. Glycerin is present in both formulæ. Axillary abscesses are not, properly speaking, dermatoses. They have been described by surgeons, notably the French, as inflamed and suppurating sweat-glands; but Unna regards them as "furuncles without cores"; that is, they form about the follicles of the axilla. They tend to relapse, but never lead to phlegmons or metastatic abscesses. The axillary abscess, if small, should be cauterized with the hot needle. If pus has accumulated it should be evacuated and then dressed with a paste of turpentine, lead, and mercury spread on a plaster.

Operative Cure of Total Ectopia Vesicæ by Trendelenburg's Method.—Heinsius reports his case in great detail. In the Trendelenburg method the separated segments of the os pubis are approximated, and having thus eliminated the tension of the abdominal wall and intraabdominal pressure the bladder, urethra, and genitals are united. The author gives a survey of the results of twenty-three operations of this sort. There were five deaths as follows: wound infection, as primary result of operation, 2; pyelonephritis and iodoform poisoning, 3. There were but three cures, one that of the author. Other procedures which utilize Trendelenburg's principle of pelvic narrowing but are more severe give a high death rate (vertical osteotomy, total pubiotomy, etc.).

Nervous Retention of the Urine.—Cohn writes briefly of this subject. Retention is seen in numerous organic diseases of the cerebrospinal axis, but in certain cases only some neurogenic factor is in evidence—either neurasthenia or hysteria. In many of these cases, however, careful study, including cystoscopy, will reveal some slight organic lesion—possibly a cystitis colli, or an enlarged colliculus, and in women some foreign body in the bladder. The author employs the manometer in these cases for differential diagnostic purposes, for if the condition is a nervous one the manometer reveals a low pressure. To cite one case a man, aged thirty-four, had been troubled for a year with the desire to urinate. At times he had to pass water every two hours. Urinary stream slow. At night he rose four or five times to urinate. There was no tenesmus. No admission of gonorrhea. When symptoms began to grow worse the author was consulted and found the bladder as high as the navel. Urine quite normal, likewise urinary passages. The condition was found to be a trabecular bladder. The manometer showed a very low intravesical pressure. Injection of 100 c.c. boric-acid solution hardly affected the manometer, while one of 400 c.c. caused strong desire to urinate and a pressure of 15.

Münchener medizinische Wochenschrift.

March 2, 1915.

France in War Time.—Madelung continues his efforts to piece together from fragmentary data what is going on in the countries of the Allies. He gives his authorities. Letters from Paris early in the war to the various British medical journals mentioned interesting data in reference to traffic. Omnibuses no longer ran. Horses and autos were commandeered. The street cars ran only during the day. Not only all able-bodied physicians but many students were called to the colors. Hospital annexes for wounded soldiers were placed in readiness. Gymnasia, school buildings, and private houses became hospitals. The civil hospitals were almost emptied of doctors and nurses. However, for fear that the city would be captured, the first wounded did not come to Paris. Not until late in August did they begin to arrive at the latter city. Chantemesse warned against epidemics of variola. Vaccination and typhoid inoculation were advised, provided for, and in part made compulsory. But few troops could wait for typhoid immunization. Ordinary sanitary measures were duly carried out. Thousands of cows were killed in the Bois de Boulogne for provisioning the city. The milk was pasteurized and used. Laws were passed against the traffic in absinthe and certain other spirits. By September 24 the population of Paris was but 63 per cent. of the antebellum figures. Americans placarded their houses or flew American flags over them. By the end of November all was changed. All fear of siege or occupation had vanished, and the city once more filled up with Frenchmen and foreigners. In the meantime, however, thousands of figures in mourning throw a gloom over the community. There is no resumption of night life, no sign of tourists. Everywhere one sees improvised hospitals. The people are not exultant, but sober and quiet. The Academy held a number of interesting sessions on war medicine, but reports are not forthcoming. Clemenceau ordered the most careful treatment of German prisoners. Many data from friendly sources show the want of efficiency of the French medical service. These concern allotment of surgeons to commands, deficient transportation service, and the like. This was greatly aggravated by destruction of railways and bridges. All these examples of neglect have been largely made good, English, and especially Americans, having come to the aid of the natives with money, nurses, and surgeons. The efforts of the Americans are not regarded by the author as unneutral, but as wholly humane. In November a contingent of Canadian (chiefly French) surgeons reached the north coast of France and established a hospital.

Light Treatment of Tetanus.—Jesionek reports four cases of recovery from tetanus ascribed by him to the use of light rays. The basis of the treatment is, of course, rational, and recognized as such through the remarkable effects upon lupus of the Finsen-light treatment. In the absence of solar light the author employs a mercury vapor lamp. He lays no stress on the concentration of chemical rays and anemization of tissues, nor on the direct bactericidal properties of light. The sole dependence is placed on the phlogistic powers of the light with their incidental bactericidal property. The author's treatment of tetanus wounds is necessarily bactericidal in scope, but this is brought about indirectly through the artificial sunburn caused by the light. Whether the latter be directed toward a sound or

diseased integument, subcutaneous tissue or muscles, there results first a hyperemia, then a copious serous transudation from the vessels. It is this saturation of the wound with serous fluid which the author believes to be responsible for the aseptic healing of the wound. Dead and dying tissue particles are destroyed while the phagocytes are stimulated to act. The result is an aseptic closure of the wound.

Deutsche medizinische Wochenschrift.

February 25, 1915.

Gas Phlegmons in the Field.—Seefisch concludes that gas phlegmons, which are particularly common after artillery wounds, lead in most cases to gangrene; yet nevertheless despite very extensive gas development do not necessarily give a bad prognosis if they are quickly attacked by free incisions extending into the sound tissues. Amputation when necessary may be performed close to the periphery of the gangrenous area, while at the same time due regard is to be had to the formation of a serviceable stump. There need be no fear that incision through a gas phlegmon will cause gas gangrene. Following these rules the author has treated successfully twelve cases of gas gangrene of severest character without a death. The majority recovered with good, serviceable stumps. The management of these cases with oxygen is difficult of execution at the front, where the remedy is used largely as prophylactic. The very large number of wounded and the pains required for carrying out the technic render this resource unsuited for general use.

Rumpf's Oscillating Current and Its Radiant Energy.—The author described his new modality of electricity in 1907 as of exceedingly great value in diseases of the heart and circulation. It is of a class with d'Arsonvalisation and diathermy. The current is obtained from a large Rühmkorff induction coil, the ultimate source being accumulator batteries or the lighting circuit. The spark gap is from 1 to 5 cm. One cm. corresponds to 10-12 volts and 2 milliamperes. Strong currents may be weakened by the use of long vacuum tubes. One pole of the inductor, the positive, is represented by the interior of a glass oscillator, while the other is connected with the patient's foot in various ways. The principal glass oscillator consists of a thin flask holding from 1 to 1½ liters and is partly coated within with staniol paper or other substance. The positive pole is therefore connected with this coating. The negative pole runs beneath a thin glass plate, isolated, and of area 30 square cm. This plate is coated below, save for a finger's breadth at its margin, with staniol paper and isolated from the floor with a strong glass plate and hard rubber. The patient's feet are usually also placed in shoes. The current is turned on with an interruption in the circuit of 60-80 per second, until the coating within the flask is charged. Oscillatory discharges at once pass through the patient. These slowly decrease in strength and are renewed from time to time by recharging the oscillator. It may be shown that this oscillatory current contains the Tesla high frequency current. The oscillations are computed to number 1,000,000 per second. In addition to high frequency oscillations there are the shocks produced by opening and closing the induction current which are transferred to the subject and affect the nerves of the skin which are not reached by the oscillations. The physical phenomena of the high frequency current are apparently slight; it gives off some heat to the tissues traversed—enough, for example, to heat 100 ccm. faucet water from 1.5 to ½ deg. C. They also have marked ozonating properties. The author now relates many experiments of various kinds made with the current.

Deutsche medizinische Wochenschrift.

March 4, 1915.

Peculiarities in the Course of Typhoid in the German Army and the Treatment of the Disease.—Grober states that no surprise should be caused by the appearance on both army fronts of actual or suspected cases of typhoid. Even in times of peace these geographical boundaries are the seat of rigid medical inspection to keep out this and other pests, and in war time, with its invasions and counter-invasions and interchange of prisoners, the dangers are greatly multiplied. Diagnosis is rendered difficult because of the various types of the disease and a large fraction of the sick is made up of typhoid suspects. The Widal test is invalided by antityphoid inoculation and is of little or no value at the front. Bacillary tests of feces and urine cannot supersede clinical finds in diagnostic value. Mortality figures give an inkling of the presence of typhoid, as does also the manner of exit, for typhoid victims die first of heart failure, next of pulmonary complications, and, finally, of intoxication of the nervous centers. In troops with their hardships and overexertions the heart presents but a weak resistance; both acute and chronic collapse are of frequent occurrence. This behavior of the heart is aggravated by overloading the stomach and colon. A typhoid case in transport does not always respond to the stimuli, baths, etc., which are of value in civil practice. The course of typhoid in the field, however, in no case resembles the disease of the text-books. At the front we see undoubted cases run their course in a few days only. Some of these readily relapse. There are other cases which run their course in from eight to fourteen days. Opposed to these are fulminant cases which end fatally in a few days. In the army we find the intestinal complications and ulcers are very rare. Hence death from perforation or hemorrhage is a rarity. Venous thrombosis is not uncommon, and this is also true of middle-ear disease and deafness. Exanthems and dermatoses are common and extensive—large, moist eczemas and other affections which bear no direct relation to the disease. To cite at random a case of military typhoid: no intestinal lesions or symptoms; moderate fever; slight bronchitis; swelling of right knee and purpura hemorrhagica. The piagnosis was purpura. Patient while seemingly doing well had cardiac failure and died. Autopsy: slight ileotyphus, with extremely flabby heart. This was all, save for the joint effusion and purpura. These patients are treated with due reference to cardiac failure. The circulation should be carefully watched from the start, and when the hardships of transportation are pending, digitalis should be given as a prophylactic. This includes all suspected cases. Alcohol and coffee may be used at this juncture. Injections of camphor oil should also be used if needed, bearing in mind the fear this remedy instills into the patient as having the force of a death warrant. In acute collapse caffein, camphor, and suprarenin should be injected. The patient should receive baths under great restrictions. They are *per se* of great value, antagonizing a large number of symptoms, but they must not be so given as to weaken the circulation, *i.e.* neither too long or of too high temperature. They may be given cool (30-25) and often, under control of the pulse. The application of cool packs at the front is of somewhat doubtful value. In regard to diet the author nourishes by calories and patient should receive daily from thirty to forty calories per kilo, to be increased even to seventy calories if the temperature is very high.

Insurance Medicine.

Significance of Pulse Anomalies in Insurance Practice.—Goliner states that recent advances in physiology have made it possible for us to study the pulse with exactitude. To be able to deduce the right conclusions from a pathologically altered pulse, one must possess a certain familiarity with the qualities of the normal pulse, such as volume, frequency and tension, along with the secondary elevations. In the normal pulse we note three elevations, but the first and third are hardly palpable; these are known as elastic elevations. On the other hand, the second elevation is much longer and much more readily palpable; it is known as the back impulse elevation and is due to the recoil of the blood upon the aortic valves, while the minor elevations are due to the vibrations of the arterial wall. In a normal overworked man the major elevation may be increased while the two minor ones disappear. This, however, is only a transitory phenomenon. In life insurance medicine the so-called pulsus durus is of the greatest importance because it is found in chronic nephritis, arteriosclerosis, and valvular insufficiency. Its prognostic significance is worse in the last-named condition. Such a pulse leads to the rejection of the applicant. To define a hard pulse one says that it does not readily yield to the pressure of the finger. The elasticity elevations are especially well marked. The hardness is owing to the increased tension of the arterial wall which is due either to its degree of elasticity or to increased outflow of blood. A hard pulse in applicants over 40 makes us think of calcification, but in the young subject it means only overfilling with blood, such as could occur in hypertrophy of the left ventricle or overloading the vessels with fluids. The hardest pulse of all is found in chronic nephritis. Pulsus durus should also suggest plumbism and valvular lesions secondary to sclerosis of the aorta.

The soft pulse suggests anemia and chlorosis, in fevers and compensatory disorders of the heart from weakened myocardium. It is often dicrotic in character. The quick pulse has no recoil, and suggests aortic insufficiency with secondary hypertrophy of the left ventricle.

The slow pulse may also be a hard pulse and then has a bad prognostic significance. It is found in mitral and aortic stenosis.

The large pulse is associated with marked overactivity of the heart and with hypertrophy. The small pulse is due to a weak systole and occurs in short-lived persons. Most of the pulse anomalies described by the writer are encountered only in severe organic disease, which would readily be disclosed by auscultation, urological examination, etc. His remarks are of value to the examiner for the accurate description of the pulse.—*Blätter für Vertrauensärzte der Lebensversicherung*, November-December, 1914, Vol. V, No. 6.

The Microscopy of the Urinary Sediment in Life Insurance Examinations.—The imperfections of modern methods of living are finding expression in our urine. Dr. W. F. Thomson, Beaumont, Texas, says that we eat, drink, and work on a six-cylinder basis, relying upon a two-cylinder renal capacity to remove our waste. Due to the nature of its function, the kidney is one of our most vulnerable points; and because of our misguided mode of living, irritants are poured through this filter that sooner or later produce structural changes.

From the standpoint of insurance it is a serious mistake to disregard the presence of small hyaline casts in the urinary sediment, even when albumin cannot be detected by the usual chemical means; they are the chief evidence in the urine of interstitial nephritis. The presence of small narrow casts signify that the lesion is situated near the outer border of the kidney in the vicinity of the cortex; medium sized casts are from the middle zone, and the larger ones are from the straight collecting tubes in the area of the pyramids.

Epithelial casts in the urine are proof positive of active inflammatory changes involving the kidney structure. The cells are the exfoliated epithelia of the tubules. Blood casts are positive evidence of renal hemorrhage and are always the result of trauma or active inflammatory processes. Pus casts in the urinary sediment point clearly to the presence of kidney lesions associated with suppurative changes and, when associated with bacterial casts, their presence is of most serious diagnostic import. Granular casts denote chronic degenerative changes in the renal structure, and fatty casts indicate fatty changes.

The presence of red blood cells in the urinary sediment indicate a pathological lesion somewhere between the meatus and the renal cortex; associated with casts, especially blood casts, it may be correctly assumed that their origin is renal. Leucocytes in the urinary sediment of men clearly signify the existence of a suppurating lesion somewhere along the urinary tract; if associated with casts, especially pus casts, the assumption that they hail from the kidney will probably be correct.

Cylindroids are composed chiefly of mucus, and their presence in the urinary sediment signifies the existence of an inflammatory process affecting some part of the urinary mucosa, and while oftentimes having their origin in the kidney, they may come also from any of the ducts of the urinary tract; and unless associated with true casts, and other evidences of renal inflammation, their presence should not unfavorably influence an opinion regarding the risk.

No examination of the urine for the purpose of eliminating undesirable insurance risks is complete without a microscopical examination of the urinary sediment. Casts, red blood cells, or leucocytes are open expressions of existing pathological lesions. While such lesions may be permanent or transient, serious or slight, lesions they are, and evidence that warrants postponement of acceptance on the part of the medical examiner until he has definitely ascertained the location and character of the lesion and its effect upon the risk.

Conclusions. (1) The usual chemical uranalysis employed in making insurance examinations may show normal findings and fail to detect the presence of important signs of existing renal disease in the urinary sediment.

(2) Casts, especially the more common hyaline casts, are albuminous products and have been preceded or will be followed by an appreciable albuminuria.

(3) The presence of casts, red blood cells, and leucocytes in the urinary sediment is direct evidence of pathological changes of the urinary system and cannot be ignored by the insurance examiner, unless these evidences are proven not to be serious or permanent.—*Texas State Journal of Medicine*, November, 1914.

Book Reviews.

Aids to Dental Anatomy and Physiology. By Arthur S. Underwood, M. R. C. S., L. D. S., Late Professor of Dental Surgery at King's College, London; Member of the Board of Examiners in Dental Surgery, Royal College of Surgeons of England; and Lecturer in Dental Anatomy and Physiology at the Dental Hospital of London. Third edition. Price, $1.00. New York: William Wood & Company, 1914.

The third edition of this well-known handbook consists of the matter of the second edition together with many important advances which have been made in dental science since our last issue. Calcification and the innervation of dentine have gone through revolutionary changes during the last two years, so Mr. Mummery's latest work on the former subject is given in an appendix. The author accepts Magitol's view of calcification which is also agreed to by Mr. Mummery, at least in its main essence, that it is the matrix and not any part of the cell itself which calcifies.

The Anatomy of the Human Skeleton. By J. Ernest Frazer, F.R.C.S., Eng. Lecturer on Anatomy at Medical School of St. Mary's Hospital; formerly Lecturer at King's College, London; and Senior Demonstrator at the Medical School of St. George's Hospital; Examiner in Anatomy for the Conjoint Board of the Royal Colleges of Physicians and Surgeons. With 219 Illustrations. Price, $6.50. Philadelphia: P. Blakiston's Son & Co., 1914.

This work is a treatise on Osteology in which the bones are considered, less as individual formations than as parts of a whole. In thus considering the skeleton, the author adds a complete account of the articulations, the cartilages which do not enter into joint formations, and the muscular insertions. The vertebral column, thorax, pelvis, limbs, and skull are considered as integers. Much space is given to osteogenesis. In illustrating many complicated structures—to cite for example the hip joint—the individuality of the constituent parts is emphasized by differential coloring. There is a complete omission of radiographs, without any allusion to this fact.

The author believes that his book is a necessary prologue to the study of the anatomy of the superjacent structures and viscera. It is certainly much more readable than the usual treatise on osteology, etc., and this alone is sufficient to recommend it. It further covers all the more minute technique of osteology, such for example as the facets of the small bones—carpus, tarsus, etc.,—so that a student of the book should be able to stand a quiz on the bones, cartilages, joints, and muscular insertions.

The author seems to imply that his work is somewhat of an experiment as a textbook, but there can be no doubt that it will be admirably adapted for collateral reading and easy reference, just as is the case with works on regional anatomy.

Grundriss und Atlas der Röntgendiagnostik in der inneren Medizin. Herausgegeben von Dr. med. Franz M. Groedel. Zweite, volkommen umgearbeitete und wesentlich erweitete Auflage. Mit 100 photographischen und 324 autotypischen Abbildungen auf 121 Tafeln und mit 283 Textabbildungen. Price, 38 Marks. Munich: J. F. Lehmann's Verlag, 1914.

The first edition of this work appeared in 1909 in a single volume of 388 pages and an atlas supplement. The present edition consists of two volumes of which the first represents 513 pages of text while the second is the Atlas proper. Despite this degree of expansion Dr. Groedel informs us in the preface to the second edition that the work has been interrupted by the breaking out of the war. The first edition had nine contributors including the author. The late Cark Beck of New York was one of these collaborators. The present volume has thirteen contributors, eight of whom collaborated in the first edition. The latter consisted of 16 chapters on regional technique, while the present comprises twenty-two. The greatest expansion occurs naturally under radiography of the gastrointestinal canal. Three subdivisions have been increased to eleven. The other old chapters show a corresponding expansion.

Among the new departures are a chapter by Schnaudigel on radiography of the eye, one by Pfeiffer on the ear, and one by Finckh on the jaws and teeth. These men are all new contributors. Pfeiffer also collaborates with Spiess on the radiography of the nasal fossæ and sinuses, mouth, and larynx. The volume fully conforms to the vast expansion and deepening of the subject during the past five yeers. One can only wonder wherein the outbreak of war can have prejudiced the completeness of the work.

Diseases of the Rectum and Anus. A Practical Handbook. By P. Lockhart-Mummery, F.R.C.S., England. Senior Surgeon to St. Mark's Hospital for Cancer, Fistula, and Other Diseases of the Rectum; and Surgeon to the Queen's Hospital for Children; late Hon. Surgeon, King Edward VII Hospital for Officers. Price, $3.00 net. New York: William Wood & Company, 1914.

The importance to the general practitioner of a work of this kind may be realized in view of the fact, as stated by the author, that nearly 50 per cent. of the population suffer from rectal ailments at some period of their lives. This book presents an interesting and practical account of the operations and methods of treatment that the author has found to be of most value. There is a special chapter on antiseptic technique and diet; the possibility of carrying out an antiseptic technique under the difficulties that prevail in rectal surgery is shown to be really practicable. A chapter on anesthesia in rectal operations is contributed by J. Blumfeld. Among the interesting features of this book are the case reports. Medical, surgical, and palliative measures are described. A large number of excellent illustrations embellish the book, which may be recommended to the student and practitioner as one of the best of its kind.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College, Philadelphia; Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price, $6.00 per annum. Philadelphia and New York: Lea & Febiger, December, 1914.

The current number of Progressive Medicine contains chapters on diseases of the digestive tract and allied organs; the liver, pancreas, and peritoneum; diseases of the kidneys; genitourinary diseases; surgery of the extremities, shock, anesthesia, infections, fractures and dislocations, and tumors; and practical therapeutic referendum. Special attention is directed to Dr. Bloodgood's contribution; his summary on shock, anesthesia, and cancer control are of more than ordinary value.

Proceedings of the First National Conference on Race Betterment. January 8, 9, 10, 11, 12, 1914, Battle Creek, Mich. Edited by the secretary. Published by the Race Betterment Foundation, Battle Creek, Mich., 1914.

The purpose of the conference of which the present volume is the record was "to assemble evidence as to the extent to which degenerative tendencies are actively at work in America, and to promote agencies for race betterment." These proceedings comprise a large number of papers, including discussions, classified under the following headings: president's address; statistical studies; general individual hygiene; alcohol and tobacco; child life; six questions; school and industrial hygiene; city, State, and national hygiene, and eugenics and immigration. This volume is a veritable mine of information on the above subjects.

Transactions of the Thirty-sixth Annual Meeting of the American Laryngological Association held at Atlantic City, N. J., May 25, 26, and 27, 1914. New York: Published by the Association, 1914.

The student of laryngology will find considerable valuable and new material in this volume. Some of the articles comprising it are as follows: "Intrinsic Cancer of the Larynx: Complete Excision Apparently Effected by Endolaryngeal Operation," by Sir St. Clair Thomson; "Limitations of Bronchoscopy," by Chevalier Jackson; "The Employment of Skiagraphy in the Diagnosis of Enlargement of the Thymus Gland," by D. Bryson Delavan; "Laryngitis Submucosa Subglottica, Acuta," by Charles W. Richardson; a symposium on Empyema of the nasal accessory sinuses in children under fourteen years of age; "The Relation of the Tonsils to Thyroid Disease," by B. R. Shurly; "Primary Lupus of the Larynx," by Emil Mayer, and "Too Optimistic Rhinology," by B. Alexander Randall.

Special Article.

OUTLINES OF A STATE POLICY FOR DEALING WITH MENTAL DEFICIENCY.*

Thoughtful people in every State are awakening to the importance of dealing with the social, economic and educational problems which have grown out of our failure to provide for the mentally defective. The present widespread interest in this subject is somewhat similar to that which, in the first half of the last century, inspired the movement to provide for the insane. An important difference between the public sentiment which brought about the firm establishment of State care of the insane and the present general interest in mental deficiency is that the former was due chiefly to humanitarian impulses while provision for the mentally defective is being urged chiefly because it is believed that such persons constitute a grave menace to the public welfare.

Various plans of action looking toward (1) preventing mental deficiency, (2) dealing more rationally with mental deficiency as a source of crime, delinquency and dependence and (3) providing more effectively and more humanely for the care and training of the mentally defective are being proposed in the different States. Many commissions have made cursory surveys of the situation as a whole in various parts of the country and a few careful studies have been made of specific phases of the subject. Legislation dealing with varied aspects of care and prevention has been proposed and not a little has already been enacted. It is believed that the New York Psychiatrical Society can perform a most useful service at this time by preparing and publishing for the information of the public a statement giving clearly the fundamental conceptions upon which we believe a sound State policy for dealing with mental deficiency should be based, together with some specific suggestions for action by the Constitutional Convention and the Legislature of this State. The Committee appointed to prepare an outline of such a statement submits the following report, giving, first, a very short summary of some of the more important consequences of failure to provide for the mentally defective; and, second, some suggestions for constructive legislation for dealing with the problems. Especial care has been taken to avoid exaggeration in stating the social consequences of mental deficiency, for the Committee has been deeply impressed by the harm done by making statements which arouse public sentiment but which are not borne out by the facts in our possession.

I. Social Consequences of Mental Deficiency.

Crime and juvenile delinquency.—1. A large amount of evidence has been collected to show that many girls and boys in institutions for juvenile delinquents are mentally defective. Just how large this proportion is cannot be stated definitely for the results of examinations made are not equally trustworthy—as shown by the fact that the number of mentally defective persons found in different institutions of the same general type varies from 10 to 89 per cent of the total number of persons examined. Careful inquiries have placed the proportion in certain correctional institutions at from 20 to 30 per cent.

2. Examination of prostitutes in the wards of general hospitals, in detention homes and in reformatories and training schools shows an even larger proportion of mentally defective persons.

3. Although the number of studies made of adult criminals have been fewer than of those of juvenile delinquents, it is apparent that a considerable proportion of these offenders are mentally defective.

4. The presence of such large proportions of mentally defective persons in penal and reformatory institutions, is undersirable chiefly for these reasons (1) because it is unjust to punish persons whose responsibility for their acts is not that of normal persons and (2) because methods of reformation, discipline and industrial training which are successful with criminals and delinquents of normal minds are ineffective with those who are mentally defective. Thus it is both inhumane and uneconomical to confine mentally defective persons in such institutions.

5. The courts, being designed to determine guilt or innocence, are generally unprovided with the proper mechanism to determine mental responsibility. Thus the presence of many mentally defective persons among those accused of crime interferes with the administration of justice.

6. As mental deficiency can be recognized at an age even earlier than that at which children are brought before juvenile courts, it is apparent that in failing to deal adequately with mental deficiency in childhood we are overlooking an excellent method of preventing crime.

7. The presence in the community of mentally defective persons, especially those who, through volitional or emotional defects are unable to exercise the control in sexual life which laws and social customs demand or to protect themselves from the advances of others constitutes an important source of moral contamination and of the spread of venereal diseases.

8. Cruelty to children has been shown to be due in many cases to the mental deficiency of parents.

Dependence.—1. Evidence is available showing that poverty is often the result of mental deficiency not only in the individual but in families in which the father or mother or both are mentally defective.

2. A large but undetermined proportion of the persons who are chronically unemployed is known to be mentally defective, their defect making consecutive useful labor impossible except under a type of supervision which is not provided in the community.

3. Vagrancy and homelessness among adults have been shown by studies of these classes to be due often to mental deficiency.

4. Mental deficiency has been shown to underlie alcoholism and drug addiction in a considerable proportion of cases.

5. Illegitimate pregnancies among mentally defective girls and women frequently render them or their children charges upon the public and constitute an important means of transmitting defective hereditary strains.

Education.—1. Although children with grave mental defects are excluded from school or are never presented for admission, many with lighter degrees of defect are to be found in the regular classes, especially in the lower grades.

2. On account of difference in the methods of diagnosis used in different studies which have been made, the exact proportion of such children in the school population cannot be stated, but it is known that the number is large enough to interfere very seriously with the work of the educational system.

Other social effects.—1. The most serious social consequences of permitting the mentally defective to participate fully in all phases of community life grow out of their inability to establish and maintain happy and well-ordered homes. High infant mortality, neglect of children, unsanitary living conditions and low moral standards characterize the homes of the feebleminded.

2. Evidence is available which indicates that a considerable proportion of industrial accidents and not a few traffic accidents, both of which involve dependence and economic loss, are due to mental deficiency in the persons injured or in those who cause such accidents.

Such a list of the wrongs which the mentally defective unwittingly inflict upon society might be greatly lengthened and to it might be added a list of the hardships and injustices which the indifference of society inflicts upon the mentally defective. Enough has been said to indicate the heavy penalty which is being paid for failure to face squarely the problem of mental deficiency and to deal with it with enlightenment and humanity. It is difficult to think of more important or more urgent tasks confronting any State today than those of devising broad, constructive measures to control the disastrous effects of mental deficiency and of speedily putting such measures into effect.

II. Legal, Administrative and Institutional Provisions.

The attempt is made in the following outline to present in more or less general terms some of the steps in a constructive State program, which, we believe, are fully warranted by information already gathered. At the same time we wish to state our earnest conviction that a large and profitable field for research exists and that a satisfactory solution of the problem, especially of those phases of it which have to deal with the detection and management of persons with the lighter forms of mental defect must wait until careful studies have

*A report adopted and approved for publication by the New York Psychiatric Society, January 6, 1915.

cleared up questions which now are obscure and the subject of controversy.

By far the most thorough investigation of the problem of mental deficiency ever undertaken was that made by the English Royal Commission on the Care and Control of the Feebleminded from 1904 to 1908. The report of that Commission made so clear the unhappy lot of the feebleminded in their hopeless struggle to compete on equal terms in the community with those possessing normal minds and showed so strikingly the waste of national resources and the grave menace to public safety which neglect of the duty of providing for the mentally defective involved that the best minds in England were enlisted in the effort to devise a comprehensive plan for dealing with the problem in all its phases. The "Mental Deficiency Act" which was based upon the report of the Royal Commission made its way slowly through Parliament; statesmen, physicians, teachers and others joining in an earnest effort to eliminate objectionable or impracticable features and to fit it for its purposes. As finally passed in 1913, this act constitutes a remarkable foundation of law upon which to develop a system of care and protection of the feebleminded.

The recommendations which follow are based in part upon this notable piece of legislation but much has also been based upon the best features of American legislation for the commitment, care and protection of the insane.

Existing laws provide us with no satisfactory mechanism for dealing with mental deficiency. If the suggestions to be made seem to involve a wide extension of present laws and methods, it should be remembered they are proposed to enable us to solve the greatest social problem which confronts the State.

General Supervision and Control.

The English "Mental Deficiency Act" provides for the creation of a central supervisory body and of certain local authorities charged with definite powers and duties regarding the commitment, care and protection of the mentally defective. In England the central body was established by consolidating the existing Lunacy Commissioners with a new Board created for the care of the mentally defective. The local authorities required were constituted by providing that the Council of each County and Borough should have a "Committee for the Care of the Mentally Defective."

Many reasons exist in this State for placing the responsibility of providing for the mentally defective, administering institutions for their care and enforcing the provisions of the law for their commitment, registration and protection upon the administrative body which perform similar offices for the insane. We have seen the care of the insane so carefully fostered by the State Commission in Lunacy (now the State Hospital Commission) that our laws, institutions and social activities in their behalf reflect the most advanced and humane ideals and have been copied widely in other States. At the same time the duties of the State Hospital Commission have grown in number and importance. It seemed to your Committee that the tasks of putting into operation a new and comprehensive law for dealing with mental deficiency, of developing the different types of institutions needed and of carrying out plans for securing adequate protection of the mentally defective in the community are so vastly important that they should be entrusted only to a Commission created especially for their performance and composed of the best-qualified persons whom the State can secure. We are convinced that the administration of institutions for the mentally defective and of laws for their protection and commitment is not a proper function of the State Board of Charities, and that the care and commitment of epileptics should be a function of a board created to deal with mental deficiency. As the present State Constitution places the supervision of the mentally defective in the hands of the State Board of Charities, an amendment creating a new Board is required. In our opinion, the adoption of such an amendment at the forthcoming Constitutional Convention is the most important and most urgent step in a program for dealing with the problem of mental deficiency in this State.

The composition of the central board is a matter for careful consideration, but we believe that the success of any comprehensive plan for dealing with the mentally defective requires that the head of such a board should be a physician trained in psychiatry and that medical men with especial knowledge of mental deficiency should fill the important executive and administrative offices. The salaries paid should be commensurate with the importance of the work to be done and they should be fixed with the purpose of attracting to these positions qualified men who will devote their lives to the solution of the difficult problems to come before them. No effort should be spared to safeguard this department and the institutions under it from political interference or control.

The head of this board and the chief executive of the State Hospital Commission, the State Board of Charities, the State Department of Education, the State Department of Health and of the Prison Commission should constitute a "joint-committee" to meet at stated intervals to consider cases which should be transferred from the jurisdiction of one of these State Commissions to that of another and to consider all matters in which the different Departments have a mutual interest. This joint committee should be given power to authorize such transfers under conditions specified in the commitment law.

It seems inadvisable to create new local authorities for the administration of a mental deficiency law if there are in existence any which can be utilized effectively for this purpose. The recent reorganization of the health service of this State has created an agency with great possibilities for usefulness. The responsibility for caring for the insane pending commitment has been assigned to health officers in this State with excellent results and we believe that the Sanitary Supervisors, provided with a sufficient number of qualified medical assistants to perform the new duties contemplated, should constitute the local authorities charged with the execution of a mental deficiency law. In those cities which have independent Departments of Health these functions should be performed by such Departments. Such a provision would do more than any other method which could be devised to remove the stigma which clings to the feebleminded. Mental deficiency has been linked to pauperism and crime too long and we believe that, in the new era opening for the mentally defective, a close association with health activities can bring only benefit to the feebleminded.*

The general powers and duties of the central board, which, for convenience, is called in this report the "Mental Deficiency Commission," should be supervising the work performed by local authorities, supervising public institutions for the mentally defective by methods similar to those used in the supervision exercised by the State Hospital Commission over State Hospitals for the insane, supervising the enforcement of the provisions in the mental deficiency law which relate to the commitment and registration of the mentally defective and their protection in the community, licensing and inspecting private institutions for the mentally defective and conducting and encouraging research into the medical, social and economic relations of mental deficiency. It should be the duty of this Commission to devise plans for the development of State care of the mentally defective and to present to the Legislature estimates for both their immediate and prospective needs. The Mental Deficiency Commission should provide for the deportation and removal of aliens and nonresidents who are mentally defective. It should see that the property of mentally defective persons is properly administered.

The powers and duties of the local authorities (special officers of the State and City Health Departments appointed for this purpose) should relate chiefly to the notification of mentally defective persons, their commitment and registration, their care pending admission to institutions and the enforcement of the provisions in the law for the protection of the mentally defective in the community. For convenience, these officials are called in this report "Medical Supervisors of the Mentally Defective."

Institutional Provisions.

It is believed that complete State care for the mentally defective—that is, full State support of all public institutions for the mentally defective—is essential and should be insured by a provision in the State Constitution. It should be specifically provided by law that no mentally defective person may be detained in

*The Child Welfare Boards provided by the Widows' Pension Act recently passed in this State might be used as the local agencies proposed in this report.

any almshouse, jail, prison, or institution for juvenile delinquents. We believe that the erection of the new institutions urgently needed at the present time should be made possible by a bond issue under provisions somewhat similar to those proposed in a bill for this purpose which was introduced in the Legislature last year. Future generations would reap great benefit from the adoption now of a broad State policy for dealing with mental deficiency and it is just that they should share in the heavy initial cost.

Two types of institutions are suggested, (1) State institutions for the continued care of committed cases and (2) State intermediate institutions for the reception, study, and classification of new cases.

1—*State institutions for continued care* of the mentally defective should each consist of a base or "parent" institution to which cases are admitted for study and classification and, in some cases, for preliminary training, and of a number of "satelite" industrial and farm colonies forming integral parts of the "parent" institution. All bed-ridden, infirm and strictly custodial cases should remain permanently in the parent institution and all other patients who on account of infancy or other reasons are unsuitable for transfer to the outlying satelite colonies. Existing institutions should be utilized for parent institutions and the location of new ones should be determined by the distribution of population and the possibility of establishing the satelite colonies under conditions most favorable to their development. Every effort should be made to increase and utilize the industrial capacity of patients. The care of the acutely sick and all medical and scientific features should be concentrated as far as possible in the parent institutions. Each of these institutions should be in charge of a medical superintendent and under the general administration of the Mental Deficiency Board.

Each satelite colony should be situated near enough to its parent institution to be within reach by a three or four hours' journey for an automobile truck. The maximum distance would probably not be more than 30 miles. Each colony should be in charge of a physician and a steward who should be an assistant medical superintendent and an assistant steward, respectively, of the parent institution. Patients should be transferred by the superintendent from the parent institution to the colonies and from the colonies to the parent institution as their condition or other circumstances require. The number of such colonies should be determined by the growth of the parent institution but, in general, not more than 20 per cent. of the total population of the parent institution and its colonies should be in the parent institution.

The law should provide for boarding-out patients in families, under the immediate supervision of any parent institution, and also for the temporary detachment of groups of patients from any colony to perform services in building new institutions or even to engage in the public works of the State in accordance with a broad plan for making the mentally defective self-supporting, as far as possible. Such undertakings should be engaged in only with the specific consent of the Mental Deficiency Commission in each instance, however, and they should be performed at all times under the supervision of physicians and attendants from the institutions.

One or more separate institutions for mentally defective delinquents should be provided and conducted in the same way and under the same administration as all other State institutions for the mentally defective.

2. A sufficient number of *State intermediate institutions* should be established for the reception and temporary care of mentally defective persons. These should be located in accordance with the distribution of population. All original commitments should be made to these institutions and, within a stated period, all patients should be transferred from such institutions to those for continued care, committed to guardians, conservators and committees or discharged. As the movement of population in such institutions would be rapid, they would be of small size. Such institutions should constitute centers for scientific and social work and should be located in cities or large towns. Each should have one or more out-patient departments which should serve as "clearing houses" for the diagnosis of mental deficiency, co-operating at all times with the courts and the schools.

Commitment and registration.—The law should provide two kinds of procedures in securing care and supervision for the mentally defective (1) commitment to an institution and (2) registration, or "commitment to guardianship," as this procedure might be called. The first sholud be based upon the best features in the law for the commitment of the insane in this State. The second involves no new principles of law, for at present insane persons may be legally committed to the care of guardians, conservators, or committees.

The law should make it the duty of poor authorities, police authorities, magistrates, educational authorities, and the heads of various institutions to bring all persons apparently mentally defective to the attention of the local health official designated to provide for their examination, commitment and supervision. In addition to those whose duty it should be to bring mentally defective persons to the attention of this official, parents, philanthropic organizations, teachers and others should be encouraged to do so whenever the existence of mental deficiency is suspected in any persons under their charge. It should be the duty of the local health official designated to act as "Medical Supervisor of the Mentally Defective" to cause all persons brought to his attention in this way to be examined, if possible at one of the "clearing houses" conducted in connection with an intermediate institution, and properly cared for pending their commitment. The law should prescribe the qualifications of medical examiners and forms of commitment. The payment of the cost of commitment, including observation when necessary should be made obligatory upon the local authorities.

The local educational authorities should be required to determine the mental condition of children of school age and to make provisions in special classes for the education of those likely to profit by such training. The State Department of Education should be given authority to require the establishment of these classes and should exercise general supervision over them. The educational authorities should be required to notify the local health authorities of any children of school age whose condition is such that they cannot be benefited by instruction in the special classes or whose environment at home is such that they are neglected or not afforded proper moral safeguards. In such cases the local health official should be required to take steps for commitment to an institution or to guardianship, but no child who regularly attends the special classes should be subject to commitment of any sort. When children reach the age when they must leave the special classes, the educational authorities should bring them to the attention of the local health official who should see that they are committed to institutions or to guardianship or discharged from supervision as the circumstances warrant. These provisions are in accord with the modern aim of the educational authorities to provide the kind of education best fitted to his needs for every child capable of receiving training.

The proper judicial officers should be empowered to commit persons to state institutions or to place them in the charge of those authorized to act as guardians or conservators. The duties and responsibilities of these guardians should be so definitely fixed that effective oversight and protection may be afforded at all times to mentally defective persons who do not require institutional care. It should be within the power of the committing authority to commit to an institution any mentally defective person who has been previously committed to guardianship when it is shown that such a person is not properly cared for or if he commits a breach of the peace.

Proper safeguards for re-examination, hearings, etc., should be provided and the constitutional rights of the individual should be carefully guarded.

All original commitments should be made to one of the intermediate institutions and transfer from such an institution to a place for continued care should be made by order of the Mental Deficiency Commission. Change from registration to commitment should be made only by an order of the court, but it should be within the power of a superintendent of an institution for continued care, a superintendent of an intermediate institution or the Mental Deficiency Commission to transfer patients from commitment to registration or to free them altogether from supervision.

The Menal Deficiency Commission should be required to have a mental examination made of all persons in prison, penitentiaries, jails, and institutions for juvenile delinquents in the State within a given period after the law becomes effective and to take the necessary steps for the commitment and transfer to an institution of all

found to be mentally defective. Thereafter it should be the duty of the chief executive officers of penal and reformatory Institutions to have mental examinations made of all inmates within a stated period after their admission and to bring to the attention of the Mental Deficiency Commission all found to be defective.

The effect of such provisions for the examination and commitment or registration of mentally defective persons would be to create a class in the community about whom especial safeguards are thrown. Lest it should be thought that this is an unprecedented proceeding, it should be remembered that this is precisely what the State has done to protect childhood and that mental deficiency is only the prolongation of mental childhood into the years of adult life. Such provisions would make it easy to enact laws dealing with many offenses against the mentally defective, very much as we now deal with offenses against children. This is just what is needed to make life outside an institution safe for certain classes of the mentally defective. The burden of public care would be lighter than if the impractical policy of permanent segregation for all were adopted, for it is undeniable that many mentally defective persons can be fully safeguarded under such conditions. A period of residence in the intermediate institutions or in the institutions for continued care would often result in fitting for such a supervised life those who would be unfit to live outside institutions, even with supervision, without such preliminary training.

When these provisions of the Mental Deficiency Act were proposed in England, zealous guardians of the liberty of the individual were loud in their protests, but the friends of the act were able to show, through the findings of the Royal Commission, what a pathetic travesty upon liberty the freedom of the feebleminded had been and opposition was silenced. As one writer said, the "Mental Deficiency Act was a real charter of liberty" to thousands of British subjects whose liberty had previously given them only the right to wander about the streets and highways of towns and villages—the butt of ridicule and thoughtless sport and the victims of lust or greed. They had come to the attention of the authorities only when the hand of crime, neglect, or debauchery had been laid heavily upon them and then they were treated by the authorities who had neglected them as criminals and paupers instead of children whose bodies had grown up while their minds had lingered in the age of childhood. In well-conducted institutions for the mentally defective these misfits are given for the first time a chance to live in a world peopled by their equals where they can find happiness, contentment, and security.

Conclusion.—There are many other factors to be considered in formulating a State policy for dealing with mental deficiency. Some of them are the adaptation to our needs of the excellent provisions in the English "Mental Deficiency Act" for the protection of the mentally defective in the community and provisions for the study of such important medical problems as heredity in mental deficiency and the relative value of different methods of diagnosis. Each of these has a bearing upon a State policy for dealing with mental deficiency, but it is manifestly impossible to do more at this time than to mention them.

We have endeavored to prevent some of the principal issues as they have appeared to us, with the thought that this society might wish, after discussion, to submit this report to the public. We feel very earnestly that the medical profession must lead in the movement to deal with the problem of mental deficiency. Legislators and judicial officers will demand medical approval of the drastic legislation which must be enacted and so we are convinced that this society has an important public duty to perform in shaping the laws upon which a sound State policy can be based and in moulding public opinion so that such laws will be enacted.

Such a statement as this of the fundamental objects which, in our opinion, should govern a State policy for dealing with mental deficiency will doubtless serve a useful purpose, but it is only an outline. To fill in this outline is a task not for a voluntary organization but for an official body empowered to obtain facts wherever they can be found and competent to weld them together into a report upon which a comprehensive mental deficiency law for this State can be drawn. This should be the first duty of a State Mental Deficiency Commission composed of the best qualified men obtainable and supplied with funds enough to enable it to make in this State an original study comparable to that made in England by the Royal Commission.

The adoption of a policy for dealing with mental deficiency in New York will involve the expenditure, ultimately, of many millions of dollars and the enactment of laws which will affect the liberty and happiness of many thousands of citizens of the State. We believe that such a policy is urgently needed and we believe that no time should be lost in obtaining the data necessary for its formulation. We recommend, therefore, that this society do everything in its power to induce the Constitutional Convention which is about to convene to provide for such a commission and to entrust to it the care and the protection of the mentally defective.

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 18, 1915

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR

THIS program was arranged by the Section on Orthopedic Surgery.

The symposium consisted of reports from different hospital services on the recent operative procedures for the deformities resulting from anterior poliomyelitis, tuberculosis and rachitis, and on the use of silk ligaments, tendon transference, astragalectomy, stretchings, osteotomy, and bone grafting.

The Development of Orthopedic Surgery.—Dr. ROYAL WHITMAN read this paper. He said that at the present time it was generally recognized as the mechanical specialty not because it was restricted to mechanical methods, but because it was concerned with the mechanism of the body, and with the diseases that disabled it. Many of these affections appeared in childhood, and involved in their remote effects the development of the body. One who practised orthopedics, therefore, should be familiar with the natural history of diseases and deformities in order to judge of the proper remedy. Operative orthopedics had been hampered in its development by lack of opportunity, and by lack of inclination and training on the one hand, and by lack of knowledge and experience on the other. It had been suggested that comparison of the operative routine at representative hospitals might present the scope of the subject in a practical manner favorable for discussion. As a contribution to this end he submitted a report of a recent service of four months at the Hospital for Ruptured and Crippled.

The number of orthopedic operations was 399; 143 were open operations. In 136 the operation was of a minor character, including osteotomies, tenotomies and the like, and in 120 the deformity was corrected by force. For tuberculous disease there were two excisions of the knee in adults, and one excision at the hip. There were four transplantation operations for Pott's Disease, and 20 corrections of deformities complicating joint disease, including 7 osteotomies.

Forty-seven patients were operated on by osteotomy or osteoclasis for the correction of rachitic deformities. There were 20 reductions of congenital dislocations of the hip, including 8 open operations. There were three arthroplastic operations for ankylosed joints, two at the hip and one at the elbow. There were five operations for ununited fracture—two at the hip, and three of the leg bones, including two bone transplantations. There were 6 open operations for torticollis. There were 63 operations for correction of deformities of the foot, including osteotomies and the like. There were 42 cases of tendon and muscle transplantation including one of the trapezius and five of the biceps. The most important group of operations was one for paralytic deformity of the foot, and classed under the writer's name, consisting of the removal of the astragalus, backward displacement of the foot, combined in many instances with tendon transplantations and fixation. This procedure had proved to be most effective in assuring permanent stability.

Dr. ROBERT W. LOVETT of Boston reported on the operative othopedic service at the Children's Hospital, Boston, for the year 1914, analyzing the cases, and commenting on certain special operations that were done.

For infantile paralysis 116 operations were done, for tuberculosis of the spine and joints 80, for congenital dislocation of the hip 31, for club foot 60, for osteomyelitis 28, for the deformities of rickets 59. Other miscellaneous operations bring the total up to 436.

Misapplied Bone Surgery.—Dr. H. Augustus Wilson of Philadelphia spoke of the adverse aspect of the results of operative orthopedic surgery, since he was convinced that greater good might ultimately be accomplished by efforts to avoid misapplication of bone surgery. The operative craze which had manifested itself in Philadelphia as elsewhere had apparently superseded attempts to avoid the risks of operation, the post-operative uncertainties, and the possibility of the production of even worse conditions. During the past few years many operative procedures had been enthusiastically advocated and extensively employed, that had later been abandoned *in toto* or reserved only for use when peculiarly applicable to existing conditions. After referring to a number of these procedures the author said that the hysteria of the present time appeared in the form of operations upon bone, especially the application of bone grafts to ankylosed joints involved in bone tuberculosis, and applying metallic plates to fractures. While such operative measures, when skillfully employed, in well selected cases, possessed many advantages, over-enthusiasm had caused them to be resorted to when the conditions were unfavorable, with results such as might have been expected. Dr. J. Chalmers Da Costa in the Samuel D. Gross Address for 1914-15 said "The surgeon, the real surgeon, is something far above and beyond the mere operator. I am convinced that knifemanship is the easiest branch of the profession, the most readily acquired, the most admired, and the most profitable financially. Young men often seek it out as a career. A man may operate with admirable dexterity and yet do very bad surgery, operating perhaps when no operation should be done, or removing, it might be most skillfully, what ought not to be removed. Real greatness in an operation is never grasped or exhibited by the mere knifeman." In consulting a physician, patients had a right to expect him to analyze their condition carefully, so as to be able to advise the therapeutic measures best calculated to afford them permanent relief. Instead of deciding hastily upon an operative procedure, he should first exhaust all means of arriving at a correct understanding of the patient's condition, and see whether conservative treatment would not be better adapted to it. As a large part of the information needed in such cases depended upon radiography, it was becoming more and more important that this means of diagnosis should not be neglected. The radiographer and the physician should cooperate in determining the structures about which information was sought, and the best means of securing satisfactory plates for the purpose. The clinician should analyze the *x*-ray findings, but in no instance should he depend entirely on the report of the radiographer. The author classified radiographs as good, bad, misleading and worthless and cited illustrations. He pointed out that in order to obtain stereoscopic plates, the same part must be exposed twice, at different angles, upon two separate plates and that if these plates were properly placed in the stereoscope and viewed with both eyes simultaneously, one blended picture, having a depth of penetration that would reveal the structure involved, would be obtained. Photographic prints taken from radiographic plates were absolutely valueless for accurate study. Lantern slides appeared, at present, to be the most satisfactory means of duplicating radiographic plates; but if they were not properly prepared, they, also, were misleading and therefore unreliable. After discussing somewhat more in detail some of the failures of bone surgery, Dr. Wilson said that in view of the large number of unfavorable results in the treatment of these bone cases, he would suggest the formation of a national society or committee to be devoted exclusively to reporting the negative or bad results of every orthopedic procedure in order that they might ascertain the reasons for the postoperative disasters, and thus avoid them. Such a society might be called "The Adverse Society" and should truthfully report the disadvantages of different methods of treatment, their failures and the deaths resulting from them. In order to lessen or prevent misapplied operative orthopedic surgery the following facts should be remembered: (1) Operations were rarely necessary in cases of fractures that had been treated on scientific principles from the onset. (2) Before operating for non-union, definite radiographic information should be obtained concerning the presence of callus, as well as that of bone atrophy involving the fractured bone or neighboring bones. (3) Bone transplants, or other operations for securing ankylosis were not applicable to the early stages of bone tuberculosis, when functional recovery might be obtained with the control of the pathological process. (4) When it became apparent that the pathological process had proceeded to an extent beyond the possibbility of functional restoration, ankylosis might be secured by either the brilliantly conceived Hibbs' operation or that of Albee of broader application. (5) Ankylosing methods did not cure the bone tuberculosis; and, therefore, they must not be relied upon solely, but must be associated with prolonged fixation and other accepted methods of treatment. (6) Before resorting to any operation, except in an emergency, a consultation should be held, preferably with the attending internist. (7) When operative procedures were finally determined upon the patient should be told the truth, the whole truth, and nothing but the truth, concerning his operation. If this information were reduced to writing and duly signed by those participating in the consultation, the total number of operations might be reduced, but the impressions that patients often appear to entertain in regard to the functional results obtainable would be removed.

The Bone Graft in Surgery.—Dr. Clarence L. Starr of Toronto, Canada, presented this communication, which he prefaced by congratulating the Committee on the place it had given to the subject of operative orthopedic surgery, which too long had been considered a science of buckles and straps and its adherents, mere mechanics. He stated that the special object of his paper was to correlate the histological and the clinical aspects of bone surgery. What was the part played by the graft and what became of it? It had been stated by a member of this academy that it made no difference what the action of the graft was, whether it was osteogenetic or simply osteoconductive. The writer felt that this point was of more than academic interest, and that the whole clinical future of this important branch of surgery had its foundation on it, and the solution of it assisted not only in pointing the way to further advances, but also pointed out the limitations beyond which they might not venture without certainty of failure. With a view to the determination of this point his colleagues, Dr. Gallie and Dr. Robertson, undertook the experimental study of the histological changes in the graft at intervals of one week from the time of implantation until the process of change was apparently complete. The findings briefly summarized were that at the end of six days the graft already showed some adhesive fixity to the parent bone but was in all respects "dead"; that was, it had no circulation, no blood vessels being apparent in any part of it and the bone cells had almost entirely disappeared leaving the lacunæ empty. The next section recovered after two weeks implantation of the graft showed the first step toward rebuilding of the graft from the surrounding osseous structures, that was, revascularization. Blood vessels could be easily distinguished, though no living bone cells could yet be found, except at the periphery. This proved conclusively that it was not correct to argue that because a portion of graft bled on recovery after a short period that it had remained alive from the time of its transference. The next specimen recovered showed the commencing osseous regeneration, and here the osteoblasts were seen migrating into the substance of the graft. There was, however, still a large portion of the bone which showed no living bone cells and the lacunæ were still empty. The next succeeding specimen showed the gradual progressive onward march of the osteoblasts and the new living bone was readily distinguishable from the portion which was still unregenerated. With the laying down of the new bone a process of absorption of the original graft was observed. The bone which was originally compact tissue was gradually becoming cancellous and the longitudinal striæ were giving place to irregularly placed trabeculæ corresponding to the law of growth of bone depending on its strain. This explained why the radiographic pictures of bone transplants would at certain stages show a lessened density, and why ultimately they assumed the density of the bone to which they were contacted. The writer felt, however, that the graft though acting as a scaffold for the conduction of osteoblasts had an additional function. It acted as a stimulus to a greater osteo-

genetic activity than could be obtained without it, as witnessed in the large amount of callus thrown out around the graft into an ununited fracture. What this stimulus was might not at present be determined, but probably it was due to the calcium content. The experiments conducted also showed why the graft which contained both endosteum and periosteum were regenerated more surely and more quickly than one of compact bone alone, and suggested that cancellous bone such as found in the rib would make the ideal graft. The function of the periosteum was difficult to determine, but it seemed fairly safe to assume that under certain conditions it had osteogenetic power, as evidenced by the reconstruction of bone after extensive subperiosteal removal after osteomyelitis. That this reconstruction might be due to a migrating of osteoblasts into the areolar tissue under the periosteum seemed most probable. Experiments were being carried on in which one-half of the graft was boiled and the other transferred fresh and no difference could be seen, either microscopically or macroscopically, in the transplants, as they both united equally, readily, and surely. The clinical experience of the writer with heterogeneous grafts was that they underwent the same process of revascularization and oseteoblastic regeneration from the bone of the host into the graft that had just been described. In no case had he found a failure of a graft of this sort to unite. If by wider experience and by the observation of others this proved to be true, it would be of enormous advantage, because it allowed of the graft being prepared at one's leisure in the laboratory, of any size or shape, to meet the requirement of the individual case. It would also do away with the necessity of sacrificing the bone of the patient and would frequently be a factor in gaining the consent of the patient or friends to the operation, where one could not get it if the bone graft had to be obtained from the patient. The author cited a case which showed that in order to get bone regeneration there must be bone contact, and that apparently this regeneration could proceed only a limited distance, and also that the periosteum, while apparently capable of regeneration, required some stimulus, before bone would form. There seemed no doubt but that grafts of any length might be regenerated, provided they were in contact with living bone at both ends, and with a strip even of periosteum among its length. Dr. Starr cited a case which demonstrated that the statement of Albee that bone of lower animals planted into humans acted as a foreign body was not correct. The author then cited three cases selected from their operative treatment of Pott's disease. He stated that their experience led them to the conclusion that the patients should be protected for a longer time than advocated by Albee. After operation all cases were placed in a half corset of plaster, or "gypsbett" and kept recumbent for quite three months, and then were further protected when allowed up by a light plaster corset or Taylor spinal brace for a time. The growth in the length of the bone took place proportionately with the growth of the child and in no case had they seen any backward bowing of the spine. In very young children whose spinous processes were largely cartilaginous the results were not so satisfactory as in older children with possibilities of greater bone contact.

Dr. Russell A. Hibbs spoke of the operative work at the New York Orthopedic Dispensary and Hospital during the past year. Five per cent. of the total number of the dispensary patients were admitted to the hospital during the year 1913 and 1914. Seventy per cent. of the patients admitted to the hospital received some form of operative treatment in addition to other forms of treatment. Thirty-six per cent. of the operative work for the correction of the deformities of infantile paralysis. Twenty per cent. was for joint tuberculosis. The remaining 44 per cent. covered a large class of cases such as rachitic deformities, deformities of the hip requiring osteotomies, osteomyelitis, osteosarcoma, arthrotomies for non-tuberculous joint diseases, and others. Among the operations in connection with infantile paralysis, silk inserts were made in 38 cases, most of them in the foot. He said that any detailed discussion of the work was of course impossible in the time at his disposal, but he wanted very much, however, to emphasize the fact that most of these operations had been done with a perfectly clear conception of the fact that in most orthopedic conditions their operations rarely finished the work. In other words, the success of their operative methods would depend very largely upon the efficiency of their non-operative methods and the same effort should be put forth for the perfection of the one as of the other. The large volume of their work must of necessity continue to be non-operative. This was illustrated by the fact that at the Orthopedic Dispensary and Hospital last year less than 5 per cent. of the patients received operative treatment, although the service was actively operative.

THE NEW YORK PSYCHIATRICAL SOCIETY.

Regular Meeting, Held January 6, 1915.

The President, Dr. William L. Russell, in the Chair.

Report of the Committee on Legislation.—Dr. William Mabon reported for the committee that the committee on legislation of the State Hospital Commission had reported to the conference of hospital superintendents and managers with the State Hospital Commission its views concerning the constitutional convention, which were: That the constitution of the State of New York should continue the State Hospital Commission, but should more clearly define its powers. The name in the constitution should be changed to the State Hospital Commission in place of the State Lunacy Commission. The qualifications of the members of the commission should be stated. It further reported that a board of control seemed uncalled for and that such a procedure, if it came before the constitutional convention, should be strongly opposed. That some provision should be made in the constitution for a bond issue for additional accommodations for the insane, and that the conference should consider the advisability of placing under the State Hospital Commission all mental defectives. The committee of the Psychiatrical Association believe that the mentally defective should be under a special commission, but if this could not be done they should be placed under the State Hospital Commission rather than under the State Board of Charities. The committee recommended that some provision be made for the observation in a State hospital, or other suitable institution, of those charged with crime, and further recommended the passage of an act by legislature for the interstate rendition of the insane.

Dr. Thomas W. Salmon said that the National Committee for Mental Hygiene had collected a great deal of information regarding the care of the insane under State Boards of Control. There were eighteen States in which the public institutions for the insane were managed by a State Board of Control, in nearly all instances without supervision by any local boards of trustees. In general, the care of the insane in such States was not efficiently carried on. It was interesting that there were distinct movements in several of these States to adopt other types of administration. In Rhode Island the State Medical Society had passed resolutions favoring a separate board of insanity. In West Virginia a bill would undoubtedly be passed in a few weeks establishing a separate board for institutions for the insane. In New Hampshire the political board of control created two years ago had removed Dr. Bancroft, superintendent of the New Hampshire State Hospital, and put in his place a man who was the author of the bill creating this board. In Illinois great deterioration in care had taken place under a board of control and the same could be said of conditions in several other States having this form of supervision. On the other hand, the treatment of insanity had made great progress in those States which had separate boards of insanity charged with this especial work. Such States were Massachusetts, New York, Maryland, and California. There were no States in which the care of the insane had reached a higher level than in these. And still in these States there were definite movements toward the establishment of boards of control. In Maryland the movement came from purely political sources and the same was largely true of the efforts made in Massachusetts and New York. In California the movement seemed to depend upon other reasons, the care of the insane not being especially in mind.

Dr. H. A. Cotton said that Governor Fort has insisted upon a board of control in New Jersey, but that the friends of the State's charities had been able to prevent such a change.

Dr. Charles L. Dana made the following motion: That it was the sentiment of the society that it did not approve having a board of control and that the society should confer with other organizations in reference to this matter. This was seconded and carried.

Dr. Mabon said that $15,000,000 was needed to meet the demands for additional accommodations for the insane and this money should be spent under the direction of the commission. The need of this bond issue was very clear. The State undertook the care of the insane in 1890, but the State had never made suitable provision for the care of the insane. There was an overcrowding of 6,000. They could not expect to get from the Legislature in one year enough money for the accommodations needed. This must be done in some other way. The bond issue seemed to him to be the only rational way to meet the situation. The idea was to first study the needs of the insane and see the amount of the bond issue needed. This would avoid the necessity of going every year to the Legislature and asking for appropriations for the needed buildings. Such a move would provide not only for the present but for the future. Dr. Mabon suggested that the committee be directed to consider this matter in conference with other committees now in existence. If then in their judgment this was a proper method to pursue they should be authorized to proceed to aid in every way possible the passage of such a measure as proposed. The late Governor Glynn recommended the passage of the bond issue and if there had been a Democratic Assembly last year this measure might have gone through. They first, however, should consider the needs of the insane. It was an outrage that the State of New York should allow 50 in a room where only 20 should be. The rooms were so crowded that in case of a fracas the patients could not be separated because the beds were so close together that they could not be gotten at. Existing conditions should be put up to the people; then there would be no question but that the situation would be relieved.

Dr. William L. Russell said that the raising of money for the care of the insane year by year by legislation was not possible; it was not possible to get enough money to care for the excess of 6000 in the institutions. The question was what shape should this all take. This was a question that confronted the constitutional convention and what was needed was a broad policy. Action by the people was required. He believed it was hazardous to go into this subject too deeply at present.

Dr. Mabon said that this question of bond issue must come up in the constitutional convention. Whether the care of the insane was included in this was a matter which rested with the State Hospital Commission. If they pointed out the necessity of providing accommodations, such as were needed, the constitutional convention might consider whether or not it was right to make such provision. Dr. Mabon did not think they could go astray in recommending additional money.

Dr. Charles L. Dana offered the following motion: "We recommend the committee to draw up as strong a statement as possible regarding the condition of the State and the need of more money; that the sentiment of the Psychiatrical Society is that some means be devised for the alleviation of the conditions now existing."

Dr. Henry R. Stedman of Boston said that he could add nothing to the plea for an interstate rendition law for New York which he had made in a paper on the subject at a recent meeting of the society. Massachusetts has the only law of the kind, but it was of little use without the cooperation of other States. It would be a great help, therefore, if a large and leading State like New York should follow suit. It was to New York City that patients escaping from institutions in other States were apt to go, where they could best conceal themselves and where they could get employment and also give their propensities full play. If such a measure were to be adopted in New York the examples set by these two important States would undoubtedly lead other States to do likewise and then they should have an effective means of protection against a highly dangerous element.

Dr. Stedman said that Massachusetts had one hospital-observation law for the criminal mental case and another similar law for the non-criminal. During the last year 149 cases in Massachusetts had been sent by the courts to State hospitals for observation pending the determination of their mental condition. It was being availed of more and more each year and was proving to be an exceedingly useful provision. These cases were sent to the hospital for observation for 30, 60 or 90 days and it was usually possible to get an extension of time for further observation if it was needed. If such a law was drawn it should not be confined exclusively to the criminal cases, which were really comparatively few. In Massachusetts since 1909 when the law went into operation, 32 criminal cases had been committed to the Bridgewater State Hospital for Insane Criminals, in a number of which the plea of insanity had been raised. The number would probably have been considerably greater if the law had been applied to other convicts whose mental condition was not recognized until they had spent some time in penal institutions. The plan of hospital observation for ordinary non-criminal, borderland or doubtful mental cases which were so numerous, especially at the psychopathic hospital, was of the greatest value. It prevented too hasty commitments and at the same time furnished the only sure means for arriving at a satisfactory diagnosis in most cases. Seven or ten day temporary care acts, useful as they were, did not allow enough time for observation except in a limited number of cases.

Dr. Mabon said that they had a civil and a criminal law. The provisions made for the civil cases must be under a separate provision. There were two distinct and separate laws.

Dr. Russell believed that all were agreed that they should have better facilities for observation of these cases and that the details should be left to the committee. They should all be in favor of instructing the committee to draw up a suitable bill.

Dr. M. S. Gregory asked if they were supposed to send an alleged criminal to a State hospital or to Matteawan.

Dr. Mabon replied, to a State institution. The details had not yet, however, been worked out. They would have to be studied out later.

Outlines of a State Policy for Dealing with Mental Deficiency.—Dr. Thomas W. Salmon, Director of Special studies, The National Committee for Mental Hygiene, Dr. L. Pierce Clark, and Dr. Charles L. Dana presented this report. (See page 665.)

Dr. Stewart Paton of Princeton, N. J., believed it to be true that much of the success of such a bill would attend its appealing to the imagination of the people, and there was much in this report which would appeal to the people and, therefore, it should be successful. But he saw far ahead and far deeper than the problem of the mental defectiveness. There was the biological problem involved and they should approach the individual at a level where he belonged. They should endeavor to take hold of the popular mind. They as physicians did not appreciate the real problem with which they were dealing. At Princeton College the other day Dr. Lowell of Harvard College delivered an address and Dr. Paton did not believe that Dr. Lowell realized the significance of what he said. He was speaking on the subject of economy and during his discussion of the subject he said that they had found, in going through the grades, that the students that had been brought up on serious charges for offenses were those above the average age of their class. Those who had committed minor offenses were students whose age corresponded with the average age of the class. The significance of this statement he did not believe struck the man who uttered it. It was a striking statement. At Princeton Dr. Paton said his experience was startling. One or two years ago he took such students as were difficult in adjustment and what he learned was startling beyond measure. All forms of psychosis nearly were represented in these students. The problem that now confronted them had a peculiar aspect. This phase of the paper was what struck him the most. He wished to emphasize the biological problem with which they were dealing in presenting this paper to the public.

Dr. Smith Ely Jelliffe said that the program sketched by the committee was very attractive. He thought by way of suggestion that it would be worth while to scrutinize the terms used, with referenee to the future. It was well known that the terms insane and insanity had grown to be extremely unfortunate ones. They carried with them the medieval idea of a stigma of some kind, something uncanny, something to be feared. It was a movement in the right direction to try to get away from these terms and hence such terms as mental hospitals, mental disorders, mental health, mental hygiene were more than justifying themselves. The words insane and insanity would probably flounder about in the cumbersome machinery of the law for several more centuries before it would seem that

they expressed legal relationships and were not useful concepts in psychiatry. Hence the word defective in the committee's report should be viewed in the light of its probable evolution and great care should be exercised that in the outlining of so excellent a plan as had been presented the progress of the work would not be marred or retarded by inept and cumbersome terminology. Terms were only instruments for handling things; hence such terms should be avoided which had a tendency to be confused with the things. Dr. Jelliffe said that it was highly desirable that all such movements should be affiliated with the central health powers. It was a sign of a civilized community that its mental health should be recognized as a valuable asset. A State Board of Health affiliation was absolutely necessary. Health, hygiene, prophylaxis, were the watchwords and the degree of intelligence of a community stood in direct relationship to the recognition given to the importance of the mental health of its members.

Dr. MABON agreed with Dr. Paton and he also believed that the public mind recognized the term mental defective and it must be used when they approach the Governor. They must at present use the term mental defective; after getting what was wished, then they could change the name.

Dr. HENRY R. STEDMAN asked if the number of mental defectives in the State had been enumerated. He presumed they would be added to the committee's statement, as the large number which would appear would be a strong argument. In Massachusetts they had a somewhat similar problem to contend with. Although they had two good institutions for the feeble-minded in the eastern part of the State, there was a movement on foot to have another in the western part. An approximate enumeration was instituted and the result was rather surprising as it showed the number of mental defectives to be within one or two thousand of the number of insane in the State. A special medical agent was employed by the board of insanity who made inquiries from all sources: institutions, overseers of poor, schools, etc., etc., all over the State. The number of mental defectives was inquired into and little or no attempt made to obtain the life-histories of individuals. The type of defect was, he thought, noted in many cases. Of course the actual number of defectives could only be roughly approximated in this way.

Dr. MABON said there were about 20,000 people in need of institutional care. The number of insane was over 35,000 in the State, that was, the institutional insane. This was an approximate estimate only.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

AT a stated meeting held March 25 in the lecture hall of Jefferson Medical College Drs. A. C. MORGAN and E. H. FUNK presented a specimen showing "Multiple Perforations of the Chest-wall in Empyema (Empyæma Necessitatis)." The patient was a woman suffering from pulmonary tuberculosis, in whom, in connection with secondary empyema, a swelling appeared beneath the left breast and after a while a second swelling near by. A fatal termination ensued, and after death it was found that perforation of the soft intercostal tissues had taken place in three situations.

Dr. P. A. SHEAFF described "A Rapid and Accurate Method of Microscopic Localization." He demonstrated a device by means of which any point on a microscopic preparation can be fixed with the aid of a mechanism attached to one segment of a multiple nosepiece, a circular impression being made on a so-called master slide at the desired point.

Dr. A. G. ELLIS presented a "Tumor of the Mediastinum and Pericardium." The heart-muscle was itself uninvolved. There was, in addition, a small growth on the anterior abdominal wall. Dr. Ellis demonstrated also "Microscopic Sections of Uterine Fibromyomata." In one of these there was a distinct fibroma in the midst of the new growth, and in another also there was an unusual formation of fibrous tissue at one point in the growth.

Dr. H. A. HARTZ exhibited specimens of "Carcinoma of the Cervix Uteri."

Drs. RANDLE C. ROSENBERGER and P. PELOUZE presented a communication entitled: "Effects of Calcium and Parathyroid Medication in Tuberculous Guinea-pigs." It was found that tuberculous guinea-pigs treated with calcium lactate, 1 grain daily with the food, increased considerably in weight as compared with normal guinea-pigs and with tuberculous untreated guinea-pigs, while tuberculous guinea-pigs treated with parathyroid gland, gr. 1/100 daily, increased even in greater degree, while yet other animals treated with both preparations increased in weight to a still greater degree. On post-mortm examination it was found that while the treated animals presented lesions of tuberculosis these were in varying stages of retrogression, while in controls there were the usual evidences of progression.

Dr. ERWIN D. FUNK presented specimens: (1) "Tuberculosis of the Brain"; (2) "Aneurysm of the Undefended Space"; (3) "Hypoplastic Kidney."

Dr. RANDLE C. ROSENBERGER presented a communication entitled "A Study of the Linen Towel from the Sanitary Standpoint." Examinations were made of towels from varying sources, as the ordinary kitchen after a day's use, from different individuals in hospital and out, as the linen came from the laundry, after use by tuberculous subjects and by patients suffering from various diseases of the skin. From the clean linen only shreds of fiber were obtained, while from the others all kinds of dirt, as well as specific bacteria and other germs in the respective cases, were found.

Drs. P. B. HAWK, MARTIN E. REHFUSS, and C. C. FOWLER presented a communication entitled "A Study of the Gastric Residuum of the Normal Fasting Stomach." By the use of a specially devised tube it was found, as the result of a large number of observations, that the normal amount of residuum was considerably more than is currently accepted, namely, somewhat more than 50 c.c., instead of 20 c.c.

Drs. MARTIN E. REHFUSS and J. A. CLARKE presented a communication entitled "The Protein Concentration of the Gastric Juice in Pathological Conditions."

Dr. JOHN A. RODDY presented a paper entitled "The Wassermann Test in Congenital Syphilis."

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE MODERN FACTORY. By GEO. M. PRICE, M.D. Cloth; illustrated; first edition; published by John Wiley & Sons; $4.00 net; 574 pages.

MORTALITY STATISTICS. 1913. Cloth; 14th annual report; published by Government Printing Office; 631 pages.

CYSTOSCOPY AND URETHROSCOPY. By BRANSFORD LEWIS, M.D., and ERNEST G. MARK, M.D. Cloth; illustrated; published by P. Blakiston's Son & Co. Price, $4.50 net; 238 pages.

ASTASIA-ABASIA.

REPORT OF A CASE EVENTUATING IN RECOVERY AFTER MANY YEARS' DURATION.

By JOSEPH COLLINS, M.D.,

NEW YORK.

(FROM THE FIRST DIVISION OF THE NEUROLOGICAL INSTITUTE.)

ASTASIA-ABASIA means, literally, lack of ability to stand and walk. The designation was applied by Blocq (*Arch. de Neurol.*, 1888) to a class of cases in which the only discernible infirmity or disorder was inability to stand and to walk, occurring in individuals whose muscle power was not detectably diminished. In other words, the individual when sitting or lying could perform all muscular acts with freedom, accuracy and power. It was recognized by Charcot and by other investigators, who soon took up the study of astasia-abasia, that it was a manifestation of the psychoneurosis which for so long had inadequate interpretation, namely, hysteria.

It is particularly since the general dissemination of, and in some measure, the acceptation of the teachings of Freud relative to the pathogenesis of the psychoneuroses (more particularly the obsessive psychoneurosis and hysteria), that a new interest had been taken in astasia-abasia.

Physicians and the laity alike are impressed when a patient who has been bedridden for years takes up his bed and walks. Narration of the following case may appease such interest and, at the same time, be a contribution to the genesis of hysteria and to its therapy.

The young woman who is the subject of the paper was 27 years old when she came under my observation October 18, 1910. She had had astasia-abasia in its completest form for four years, and for seven years she had been a confirmed invalid. In these long years transformation had been wrought in her character which I shall attempt to sketch in outline. At about thirteen years she began to suffer from "blinding" headaches, accompanied by disturbance of vision. These attacks became more frequent as she grew older, her sleep became poor, she became "whimmish" and weak. Menstruation began in the thirteenth year and continued regular for upward of a year. She had received no instruction concerning its significance. She does not recall that she was particularly frightened by its appearance. Her first knowledge of sex came soon after, but she does not admit that it made particular appeal to her or that she was curious about it or its significance.

About this time she had the first attack of hysteria, which was precipitated by a violent outbreak of anger accompanied by tumultuous profanity on the part of her father. She doesn't know why the profanity should have upset her, although she had been taught that profanity was wrong. It may have been her father's manifestations of anger and rage in other display than the profanity that frightened her and left her feelings shattered. Whatever it was, she pulled herself together very slowly after the occurrence. The hysterical manifestations were inability to keep still, twitching, crying, and profound mental agitation. These lasted the entire day, and possibly longer. About this time of her life she began to read poetry, and liked especially lyric verse; heroic love appealed to her very much, and she felt that her capacity to make love was comparable to that described in the poetry she read; love that leads to sacrifice, to superhuman effort and action, love characterized by unending devotion capable of display on proper appeal was latent within her, and only the occasion, the opportunity, was necessary for it to display itself. Her surroundings were not congenial to her tastes, and the young persons she met were not of her stripe, although they were of the station of which her parents were. She was not interested particularly in the young men she met, although she romanced about the coming of her special Lochinvar. She denies a knowledge of any particular sex interest at this time, or appreciation of sexual matters. She was conscious, however, of distinct libido on reading poetry and on romancing, and at times on going to church, but she does not admit any voluntary act that can be construed as masturbation. She had pleasure in her emotional states, induced in the way previously mentioned, but it was a pleasure she could have shared openly with others, had there been a worthy companion. It was about this time that she had first experienced difficulty in walking; her legs tired easily and she got tired all over. She began to have pain constantly in one place and another, chiefly the knees; the left leg seemed to shorten and she walked with a limp; the pain progressed up the hip, over the side and into the shoulders. She was able to get about the house all the time, but seemed very tired and fatigued upon very slight exertion. The fact that she could not work disturbed the atmosphere of the household and precipitated altercation between her mother and herself, but she could not see her way clear even to make an attempt to do it when she felt better. Self-indulgence came easy to her, and the more she coddled it the more righteous she felt. Sometimes, and especially at the menstrual period, she would lie up for a week. This interfered with her attendance at school, and she was not promoted. She felt a great disappointment in this, because she estimated herself very ambitious. She wanted to extricate herself from the social sphere of her parents; to become a writer, or a teacher, or in some way attract attention to herself and to her abilities. She is conscious now that at this period she was critical not only of persons, but of her environment. She was, moreover, censorious, but she

does not recall that she ever asked herself what she had to give to the one who should come along and help her to the stage or arena where her talents could be displayed and appreciated. She does not admit that she had any frights to her modesty at this period of her life, or earlier, and repeated prolonged investigation, under the most favorable circumstances, that is, when the rapport was fully established with the interlocutor, in favorable environment failed to reveal any incident in her life that could be so construed.

When she was thirteen years old she learned about creation of human beings. She had read physiology in school. She knew when people became married they entered into relationships which led the wife to have a child. She does not admit that she had any morbid curiosity about it, or that it fussed her very much when she thought that such might be her fate. She admits thinking about the matter, and about the intermediate phases of sex relation, and often to have had libido as the result; but she never indulged in masturbation in the ordinary acceptation of the term.

In February, 1903, she had an attack of severe pain in the right side. This occurred suddenly and she became unable to walk. Four months later she was operated upon for appendicitis. The right leg at this time was alone affected; the left remained as it had been and she was able to walk with a cane. At seventeen she began to have violent dysmenorrhea. The general pain that she had later was augmented at her menstrual period, which became worse and worse. At the time of her first operation she had been told that the right ovary was diseased; this was removed in June, 1906. The left leg became affected afterwards.

Before this operation she kept her bed about two weeks of each month. From now on she remained there more and more, so that for upward of four years she had been completely bedridden, and practically so for seven years.

She feels that everything has been done to make her well that can be done, and despite it all she is in this hopeless state. No one understands her, and every one who attempts to cure her does so by force. Nurses are cruel to her, doctors are mandatory, heartless, and obtuse. If she could only make them realize how important it is that everything should be done in the way that she is convinced is right things would go smooth and even—like with the dead, if they could only come back and be forgiven. "I am so afraid of people who have hard, cross voices, and who speak as though it were a great burden to do anything for me; as though I were a great trouble to them," she writes in one of her notes which I soon began to get daily. The physician who sent her to me wrote: "During the four years she was under my observation I regret to say no systematic effort was pursued, as she lived at considerable distance from the city. * * * Suggestion and hypnosis have been absolutely ineffectual. * * * She had been persistently urged to believe that her condition was one that would eventually be completely recovered from. Her mother devotes all her time to her, most conscientiously, but believes that the girl is feigning, and the girl knows it. She is thus, as it were, required to continue her symptoms to prove their reality."

For several months she was in a sanatorium, where it was noted that, when an attempt was made to have her stand, a nurse supporting her on either side, the knees flexed like a hinge and "it seemed the contraction of the muscles produced an opposite movement to the one that was attempted. In other words, there is a marked motor negativismus. She becomes angry when attempts are made to have her stand or move, and all such attempts cause palpitation of the heart and apparently profound dpspnea. The patient is most unsatisfactory to deal with. She must be lifted as a dead weight, and already she has worn out two special nurses."

When she came under my observation and care her chief symptoms were, in addition to the astasia-abasia, those of fright, terror, bewilderment, incredulity, and despair. Her attitude toward people and things was topsy-turvy. She was afraid of nurses, distrustful of doctors, and radiated the "nil admirari." Being completely helpless (save her hands, which in time she thought would become helpless also), she required much care, and if attention were not given to her at once she would become persecutory. These ideas took possession of her, and her conduct was entirely in conformity with them.

She was said to be of average intelligence, given to reading good literature, including poetry, and that she had "ideals" of life somewhat more ambitious or exalted than her comparative humble origin and environment would seem to warrant.

Physical examination failed to reveal any abnormality save an infantile, wholly undeveloped uterus; reduced corneal sensibility, fatigue fields, and a mild degree of astigmatism. (The right field was much contracted concentrically for color, slightly for white; the left for both white and colors.) She was fairly well nourished, and laboratory examinations of the blood, stomach content, and excreta were negative.

The first three months of her stay in the hospital were devoted to a study of her early mental and emotional life. The first shock that she was able to recall after many seances was one when she was seven years old. It was a game of hide-and-seek in the barn. Her playmate, a boy of twelve or thereabouts, "found" her in a remote part of the haymow and attempted to unbutton her drawers. She was terribly frightened, though she had no idea of the significance of the act then. She didn't tell any one, and was afraid some one might find out about it. She doesn't recall worrying about it. It made no profound impression on her and she forgot it. For the past few years she has realized that within herself there are at least three distinct personalities which are warring, and the combat is so incessant that she has no peace of mind, no time or capacity to do anything else, except give heed to the strife that is going on within her.

This in a brief and sketchy way must suffice to convey the mental and emotional state in which she was when she first came to the hospital.

After many "long talks" with her to display the pattern of her mind and emotions, and to elicit her attitude toward life, her obligations and her duties, and to give her opportunity to recount her disappointments and to project her ambitions, an attempt was made in simple language to describe the genesis of voluntary movement. It was pointed out that such movements follow excitation occurring through one of the special senses, an expression of the will, or the result of subconscious excitation. Fear may inhibit or prevent such movement, and particularly prevent movement which is initiated by the will. Simple examples were furnished, and

the patient seemed to fully understand what was said to her. It was further pointed out that such inhibition of movement is a protective, or a protecting, effort on the part of the consciousness to cover up some complex or conviction, which one side of the individual's mental makeup desires to have covered.

After this explanation, another pointing out the destiny of the individual was undertaken. A simple explanation of evolution, of the customary myth of creation, and of the reproduction of the human species was made. The manifest object of the individual is to discharge his physiological destiny—to live and to reproduce. His moral destiny is a varying quantity and depends upon the enlightenment of the individual, and upon his intellectual and emotional possessions. One should have no more hesitation in discussing the physiological destiny than social destiny or moral destiny. We make the closest approximation to our Creator by perpetuating His image; the creative capacity links us to God, and our chief pride of existence is to be taken in this possession. If this reasoning is sound, then everything connected with creation should be a matter of pride, not of shame.

On another occasion an attempt was made to explain to her that her disease was a functional, not an organic one, that it was called hysteria, and that hysteria is not so mysterious or the reason of its being so unsolvable a riddle as is currently believed. It is in reality a splitting off of personality from that composite possession known as individuality or personality, until the individual may seem to have not only a double but a triple, or even a quadruple personality. Each of these personalities may be distinct in its delineation, imperative in its activity and determination, and uncompromising. An attempt is made to explain that it is the warring of these errant personalities, plus the fright, that are at the bottom of the excitations and inhibitions that constitute the framework of hysteria, and which are the direct fundament of hysterical manifestations. The patient is assured that as soon as these wandering, malign, errant personalities are brought back into the fold, and welded together to form the composite which constitute the individual, the ego, that the normal personality will then dominate the actions of the individual in a harmonious way, or at least with such harmony that it may be called normal. As soon as this occurs the individual is well; that is, he or she does not display phenomena that are abnormal.

This conversation was repeated to her many times when she was found in receptive mood, and many simple illustrations were cited to facilitate her grasping the underlying principles. Diagrams, models of the nervous system, the skeleton, patients that presented paralysis of one or more extremities were made use of, until finally she seemed to grasp what we were trying to convey to her.

Many efforts were made to have her narrate her dreams. At first she had some difficulty in doing so. She would say: "I dreamed something very disagreeable. I remember seeing a coffin with my brother lying in it outside the dining room window. I dreamed of seeing my father and my brothers, and saw them doing things as though they were alive, and yet in my dream I knew that they were dead."

Gradually she developed more facility in expressing the transpirations of her dreams, and would write the details of them. A few of those are herewith appended. Any one who can trace the genesis of her infirmity and its manifestations in these will find documentary proof of a beloved theory; others may find in them simple parallels to their own experience.

I.—I was alone in a large place that was dark and empty with many long, winding passages in which I could not find my way. I kept trying to find a way, but my head only went around and around and I only got confused and bewildered.

II.—I dreamed I was at the ———. We did a great many strange things about the house, and when we went out on the veranda it was all mud tracks. I started to go home, and out in the roadway I met a drunken man. He stood right up in the middle of the road and voided. I tried to run back to the house, but he would not let me, and he chased me back and forth from one side of the road to the other. Finally he made a "grab" for me and I screamed and woke up with my heart beating so fast, and I was wet from a profuse sweat.

III.—I had another dream after that. I was at a business house alone in a great empty place, where it was dark and cold, and I had lost my way, and I kept wandering around and around, but I could not find my way out. Often I dream of falling from high buildings, and I can feel myself falling down, down, down—sometimes I never strike ground at all; I wake up while I am falling, and sometimes I wake up just as I strike something.

IV.—I dream so often of doctors, especially of Dr. ———, who operated on me the first time. He was so rough and brutal and frightened me so. He was always trying to *make* me walk, and sneering at me, laughing and making fun of my attempts to walk, and telling me I could walk if I wanted to. I am so afraid of doctors. In my dreams they are always bullying me and making me do everything, and they speak so cross and scold. They are trying to operate on me, and they are giving me ether, and they are holding me down on the bed and I am suffocating.

V.—Sometimes I am in deep water drowning, or rather struggling against drowning, or I am getting smashed in railway wrecks, and I am covered with blood. I can see the blood streaming over me. Often I dream I'm dead. Once I was lying dead in a coffin. I could see it just as plainly, and could see just how I looked and the white dress I had on. But I was not buried; the coffin was standing on top of the ground in a lot in a cemetery. Outside there was an iron fence, and shrubs grew close to it. Then "living" I was standing by the fence picking flowers off these shrubs. Often I am that way—living and dead at the same time.

VI.—There were two high towers made of lattice work. They were on the bank of Trout Brook. All the pictures in my room were off the walls and I couldn't find some of them. Mother was rearranging those on the east wall and there was not room for the "water color" or the Dutch scene and I wanted them on that wall. I was on the long lane that leads to the little red house that is set way back from the road on North Main street. There were people with me, but I don't remember who they were. I saw a fence and some one sitting on it. The grass in the fields was very long. The wind was blowing across it, and I saw the grass swaying. Some one was trying to do something to me. I saw snow. They were making me go somewhere. I saw my brother and ——— and a number of other people.

I was at home and was sitting out in the bathroom. The door that led into the kitchen was closed, but I could hear the voices of people who were talking. I thought ——— (a person whom I have not seen or thought anything about for years) was there, and he was smoking a big cigar. The people seemed to be waiting for something that was to happen, and ——— wanted my brother to go for a drive. Then I saw the interior of a big public building. It looked like a theater, and some entertainment was going on. I saw a great many children as I passed down the aisle to find my seat. I was with some one and we were in the upper balcony trying to find our seats. I heard water dripping and every one seemed to be looking around to discover where the sound came from. Next, I was right in this room, in this bed. I was lying on my side and my knees were drawn up. Two nurses were standing at the foot of the bed and they were putting some sort of machine on to the soles of my feet and screwing it into the flesh so it would hurt me. I screamed and

screamed and tried to draw myself away; but they only pressed the screws in tignter and bent my knees until they touched my body. And oh, how they laughed because they hurt me! I struggled and struggled and tried to call for the night nurse, but my voice wouldn't come. I couldn't make a sound. I woke up and saw the light in the room. I was just in such a position and I couldn't move a muscle. I thought I must be paralyzed. I wanted to ring for the nurse, but I couldn't move my hand to reach the bell.

Sometimes after relating a dream she would pen a few reflections or desires, such as the following:

I don't like to leave Miss ——— (the head nurse), but I would like a room with some sunshine in it. It would be more cheerful and I could see to read and write without straining my eyes all the time. I wonder where that car goes! It makes a lot of noise. The window ought to be open more. Miss ——— has a very nice voice. Sometimes I am afraid of Dr. ———. I was not to-night. I wonder if I have got to tell him everything! If I tell him what I can't do, or where I can't help myself, I am afraid he will make me do the things, and that only makes me nervous. I will never get well that way. It is just what Dr. ——— did to me—all the time—just give orders and make me do things. That is just plain bullying and nothing else.

VII.—I dreamed of a dense wood, where I was trying to find a path. I remember looking up to the sky and seeing the sunshine. It was so bright as it streamed through the opening over my head. Suddenly I saw straight ahead of me a long, narrow path. There were trees on either side of it, and they were glorious with autumn colors — red and gold — shimmering in that brilliant sunlight. It seemed to be near the Bishop's house, and I remember seeing Gertrude. Later I was up on a hill, looking down on a large expanse of water. It looked very dark and cold. There were boats on it, but I can't remember what sort they were. Helen was standing beside me and she was urging me to do something. It seemed to concern the water in some way. I thought we were waiting for her husband, and he was coming on the water.

VIII.—One night I dreamed that Dr. ——— was standing over me with an ether cone and was making me take ether and I could not take it. I tried to breathe in it, but it choked me so and something seemed to be cut right off in my nose, and I heard an awful screaming, yelling noise in my ears. Something was pressing down on my stomach, and I tried to push it off and called Dr. ——— to please take it away. Then I woke up, wet with sweat, and my heart beating so fast I could scarcely get my breath. I was so frightened and I didn't know where I was. I thought I was on the operating table down at the ——— Hospital. It took me such a long time to find out that I was at my own home in my own bed and that the furniture in the room was all there, just as it always was. After a while I went to sleep again and I had the very same dream all over again, and woke up in the same fright. I did that same thing five times that night, and the last time I waked up, I burst out crying and called for mother and told her that I would not try to go to sleep any more, because I only dreamed I was taking ether just as soon as I got to sleep and it wasn't any use. It was all so real and distinct. I could hear the doctor's voice and see everything around the operating room and hear the rattle of instruments.

IX.—Another time I dreamed I was in a room that was strange to me. I had never seen a room like that anywhere. It must have been a doctor's office, only there was a bed in it. The bed was standing along the east wall—a little white bed and I was in it. I had been having a baby. On the south side of the room there were two windows and between the windows was a white sink that stood quite high. Dr. ——— stood there washing his hands, and beside one of the windows stood a strange man. He was very stout and had red hair and little squinty eyes. He was talking and kept insisting that I had had a very hard time. "Oh, no! It was nothing in comparison to what I had suffered at my menstrual periods." And I got out of bed and walked all round the room with the doctor holding me by the hand, just to show that man that I was all right. I woke up just as the doctor was leading me up to the side of the bed, and I looked all around the bed for the baby and the doctor, but I couldn't find either one of them.

It is not my intention to attempt other interpretation of these dreams than the obvious.

The substance of the first dream is the predicament in which she finds herself as the result of her illness. The second is concerned with an actual experience that shocked her. The third her predicament again; groping to find her way out. The fourth reveals the conflict which endeavors to bolster her position, viz., that she will show the doctors that she is right. The fifth that she is no longer able to support her state. The sixth her predicament to find her way out appears again. As a matter of fact all her dreams have the same theme: groping to escape from her prison and revival of her experiences, or furnishing contrasts to convince others of her profound suffering.

"Telling everything" resolved itself into discussing freely her multiple personality. After long and repeated discussions about this matter it finally crystallized into her admitting that she (one of the personalities) was going "to tell" on the other two. "It is really taking a mean advantage of the eight year old—giving it against her wishes. But I had to, because I promised to send it, and I never, never break my word." "You know, she destroyed the other list I made for you, because she didn't want you to have it." "Please remember when you read this that the eight year old furnishes all the comedy part of existence." "Without her life would be only heavy tragedy."

Person No. 1.—She is about eight years old, and physically she is pretty weak, but she has a much stronger will than the others, and she has a very determined way with her. She has an enormous appetite, sleeps well, but dreams continuously, and her dreams are a jumbled mess of silly things. Whether this is the one that suffers least of all, I am not certain.

She suffers intensely with her head and nerves. She is very, very sensitive; indeed, she seems to have the power of feeling things that are going to happen to her, and she can feel people near her even when she cannot see them. All her senses—sound, sight, taste, feeling, etc.—are highly developed, but she seems insensible or highly indifferent to the higher, bigger things of life. She has a passion for clothes and jewelry; nothing pleases her more than to dress up and curl her hair. Childishly frank and affectionate, she craves the affection of other people. If she can have her own way she is pleasant and agreeable; but when she is crossed she is irritable and shows a decided "fighting" spirit, and she is often rude and quarrelsome. She is terribly suspicious of people whom she dislikes. She is tricky, very imaginative, bold, dashing, and very witty.

Person No. 2.—She is very, very old, about ninety I think. Physically she is so weak she can scarcely move. She cries a great deal, but I think she suffers the least of all. She has no appetite whatsoever. She lies awake at night for hours, and sleeps only from sheer exhaustion. Even then it is only a very light sleep, and she has hideous dreams that terrify her. She has the same degree of sensitiveness that No. 1 has, and she can feel things that are going to happen to her. Although she feels people who are near her, this sense is not so acutely developed as in No. 1. She is abnormally good, but thinks she is an awful sinner. She is very morbid, filled with anxiety, and worries and broods over everything. Although she has an excellent mind and a good memory she is timid, afraid of everything and everybody and most fearful of losing people's good opinion. She is yielding to the point of weakness; always gives in when there is any argument or discussion. She never quarrels and never explodes. Quiet and reserved with acquaintances she is quite frank with her friends, and is pleasant and kind to everybody whether she likes them or not. She is interested apparently in everything that concerns others, but her interest is really superficial. She suffers terribly with her head.

Person No. 3.—This one is twenty-seven years old (the patient's age). She is the strongest. She has a fair appetite, sleeps moderately well, but has hideous dreams which she does not seem to mind at all. She has a splendid thinking, reasoning mind, but a poor memory. She is very practical and sensible. She is not at all sensitive. She seems quite normal in every respect save

one—she doesn't care about anything. She is perfectly sensible of everything, knows right from wrong, and good from bad, but she merely doesn't care. Nothing ever seems to make any difference—she doesn't care whether she lives or dies; it is all one and the same to her. She suffers terribly. Although she has a consciousness of having existed before in some previous state, ages and ages ago, she has known every human experience; she has felt every human emotion and passion. For her there is nothing left in all the world—nothing! There are days when she feels as though she were walking in a dream, her mind dazed, and not consciously connected with anything. At other times her mind is clear and fine and as strong as a mind can be.

Person No. 4.—There is a fourth one—the "nice one." I do not know anything about her except that she laughs right out loud when she comes on the scene.

At another time she writes: "I do not know whether it is No. 3 who suffers most during the menstrual period. There is one thing the three are agreed upon: they all have a passion for art. They like the same pictures, and all like to read about art, though, of course, it is above No. 1's mind. They are all fond of poetry. In their 'wild' moments they contemplate writing a book. They do not like the same people. No. 1 and No. 2 have strong likes and dislikes, whereas No. 3 has a different opinion of the others. No. 3 hates No. 2, No. 1 hates No. 3, but No. 2 thinks No. 1 is a nice little child and should be left alone and not bothered."

At another time she writes: "No. 4 was on last night, and she is a glorious creature. I wish I could always be here and never any one else. The other hateful twenty-seven-year-old one had been 'on' during the day with her tremendous mind and her still more tremendous indifference, and then something happened, and as quick as a flash the other one came on—the eight-year-old one." . . . "Oh, but she is quick and strong, young and glad of life, with the sunniest disposition in the world and a beautiful character. She is perfectly normal and natural, except she has an awful grudge against Dr. —— [the physician in her home town, who has taken care of the patient for many years]. When she came she just wouldn't write anything, and now that she is gone I cannot remember a thing, she tired me so; I just feel dead and my head hurts frightfully." . . . "She is so strong and moves so rapidly and does things so like a shot that she keeps me gasping for breath. I think it would be the easiest thing in the world for her to get up and walk and dance or do anything else she wants to. Why doesn't she do it, I wonder? There is something in the way.

"Was I that one before I got sick? Everyone says she was bright and clever, jolly and sweet. Now she is so full of mischief, with a keen sense of humor and so interesting in everything and everybody. She is strong in her passion for she loves and hates, but somehow there is a good deal of charity in he opinions of people. She sees all their good points, except perhaps those of the doctor. She is gone now, and I can't get her back. She is just as illusive as the pot of gold at the rainbow's end. The doctor says that I can control her, but I cannot. If I could, I would be her always. I would give anything in the world to be her, because life means something to her, and she wants her life to mean something. You see, I am 'on top' now, and I don't believe I want to be all 'cast iron' self control anyway. I'd like my mind to control the movements of my body, but not my feelings or emotions. Why! if I did, I'd be as hard as *nails*. No, I'd like to be something besides a body and mind and self-control. I'd like to be just a *human being* with a strong, well body, an eye that sees, and a heart that understands and a *soul* to rule over all.

"No, it's an impossible standard that Dr. —— has set for me and then, when I fail to reach it, he will sneer (inwardly) or, worse still, be disappointed, and that's the last thing to finish me. The real thing of it is that he is perfectly helpless. Queer, isn't it, that any one as clever as he can't find a way to help me out of this awful misery!

"A long, long time ago, I read somewhere that 'human misery is as much of a disease of mankind as any of the other ills to which flesh is heir, and that there should be physicians for human misery just as there are physicians for disease.' And who, but a doctor, would be better suited to heal sick bodies and sick minds and sick souls! Why dissociate the three? Oh, I know that a doctor would say that it is outside his sphere—leave that to the minister; but the ministers don't know 'life' the way a doctor does. Theology teaches them a lot about divine nature, but when it comes to plain every day, *human* nature, they are mostly always 'stuck.' They worry along just the same as the rest of us do—worry and fret and grumble, too, and try to preach Peace, when they haven't got it themselves. Except the dear old duck of a chaplain. He had 'Winter' on his head, but there was 'Summer' in his heart and a whole lot of it, too. Every human being was his brother and he *lived* and talked and fairly radiated peace—a sort of a 'living benediction.'

"I'd rather pay a doctor five dollars for bringing me peace of mind than for giving me a handful of pills any day; for the pills would only last a couple of days, while the 'peace of mind' would last a good while. What's the difference between a sick body or a sick mind anyway? I've no right to his 'personal' time, but I have a right to his business time, if it's paid for, and there's no reason under heaven why it should not be.

"But the 'angel' doctor is gone, and this other one will never in all the world be able to help. And so he shoves the whole thing off on to my shoulders and calmly 'washes his hands' off the whole affair. But it is too big a contract for me to tackle all alone. It gives me just the sort of sensation that I'd imagine would come to a prisoner at the bar, when he is given a verdict of 'life imprisonment.' Oh, yes, I know that I am the architect of my own soul, but the architect's dream never becomes a reality, all of itself. He has to have a lot of material aid—many kinds of building material and many workmen to help, before the dream takes form. And I cannot even hire help—there isn't any, anywhere. No one will *take the trouble* to help, and I am so utterly alone!

"I've waited and waited—past hope, past patience, past caring—until the heart in me is dead, and Oh! how I wish my body were so, too! No, I don't want to be pitied—I hate that! I'd only like a little 'understanding,' for I haven't had a bit since I lost brother.

"Oh! I'm so bored with life! It isn't right to be so bored with life, but somehow, I can't seem to help it. Nothing in the world has any meaning any more, nothing seems to make any difference. Everything I used to love has gone stale, it's all just alike. There's no taste left to anything; all the fragrance, all the rhyme, all the harmony has gone out of life. There isn't anything there! It's just empty, empty, empty.

"And besides, my head isn't right—it pains so, and is so queer and confused and dazed—feeling all the time. Sometimes, when people are talking to me I don't know what they are saying—there's nothing but a hideous blank. And sometimes, I can't 'remember' at all. And I can't sleep at night. I worry and worry because I can't get out of this awful condition I'm in, and I worry because Doctor 'preaches,' and I worry about mother, and I worry for fear something will happen to Billy.

"And then, when I do get sleep, I have such hideous dreams: I dream I'm dead, and it feels good; and I dream doctors are cutting me up, and it feels good; and I dream they're 'etherizing' me, but I don't mind; and I dream of jumping off from a high building, and I dream of drowning myself, and I dream of throwing myself under railroad trains, but I never, never seem to mind. Nothing in the world seems to matter. Oh! this awful emptiness! I can't stand it any longer, I simply *can't* stand it. I wish I were dead, but I can't seem to have even *that*, and yet there are so many easy ways to make one's self dead. Oh! *make me*, make me want to live!

"Once upon a time (that is the way in which all nice stories begin)—once upon a time, there was a doctor who was an 'angel' doctor. How do I know? Oh! once when I was very sick, he took care of me—the very best care that a doctor ever took of a patient—and I found out all about him. He was young and *alive*, so thoroughly alive—just brimful of joy of living! And he had the nicest face, with sincerity, and sympathy and integrity, written all over it. Kind, honest eyes, and a wonderful health-warming smile, and a voice that could tie one to life—one couldn't have gotten away from it (life, I mean) if one had wanted to; but there, no one ever would have wanted to die—one longed to live, grandly, superbly!

"Somehow he made it such an awful lot easier. Life seemed less of a drudgery and very much more of an opportunity—living wasn't just a *necessity!*

'Twas an art, and the highest art of all was just this: To take life the way it was and make the best of it.

"And he was clever—oh! so clever, and as good as he was clever (and I never knew any one half so clever). Kind and courteous, with a fine big 'friendliness' of manner that went with it all—*he* never laughed in the wrong places, he was too considerate for that—so fair and just to everyone, always. I think, he tried to 'put himself in the other fellow's place' and when he couldn't do that, when he just *couldn't* understand, why—he waited, until he could, or the 'other fellow' did; just waited, all patience and gentleness, and compassion—ah! one knew instinctively, that he was a 'working partner' of the great Physician.

"And then one day something, something (?) happened and he went away—and that's all—except that he wore blue suits and red neckties.

"When I get well, I'm going to have a big black hat like the one Selma had on with two long plumes drooping off the brim on one side—one black one and one pale blue one, and just too soft and silky for anything—and a wreath of green leaves around the crown. She let me put it on, and the girls said it looked simply 'stunning' on me. I turned around and looked in the mirror and it did! It is so long since I've had any 'clothes' I'd forgotten that I could look like that in anything—say nothing about a hat!

"But come to think of it, if I'm going to be a trained nurse, I don't suppose I'd have much call to wear a hat like that. Still I guess I'll have it anyway—it would be a perfect pleasure to take it off the closet shelf and look at it, and besides, I could wear it when I was 'off duty.' Then I'd walk in to my patient and let her see how I looked with something else on besides a uniform.—I always liked to see how nurses looked in street dress. Some of them would look just great and some of them would look like the same darned old maids—I never said that word before, but then, I'm not saying it now, I'm writing it —but, I never wrote it before, either. It looks lots better than 'the dickens'—I guess I'll say it again, sometimes it will make the others awfully mad— They're such pious parties they don't like people to talk that way. But, I guess I hadn't better say it, either, for they would probably be so mad, there would be no living with them, and they almost drive me crazy now.

"Do you know, I know just how those people in the Bible, who were 'possessed of devils,' felt—I have got three devils and one angel. I guess we devils are 'running things' most of the time—but I don't mind being a devil one bit. I'm tired of those goody, goody saint things. Say, did you ever go to church four times on Sunday and the way I used to do? (*Every* Sunday). Then sometimes I'd go downtown to 'vespers,' besides, to hear the music—which made five times.

"Out at tht sanatorium, they had prayer meetings sixteen days a week—but I never went. I stayed out in the park and flirted with Prof. L. But it was a grand old place, just the same, and they had ice cream every day. I liked that. Today we had corn fritters for dinner. I ate seven. I expect I'll have the stomach ache.

"If I were well, I'd take a hospital training and work and work and work, so I'd never have a chance to think. Oh, I'm so tired of doing nothing but thinking and 'loafing!' I want something that will fill up all my time and mind and life. And I think nursing would be just about as hard as anything I could get —I'm sure that would keep me busy all day long and get me so dead tired, besides, that I'd just *have to* sleep at night—sleep from sheer physical weariness and only wake in time to dress and then go at it again—day after day after day, just *work!* I believe it would be the making of me—I'll bet i could do it—just you wait and see! Oh! I have promised Martha for ages and ages that I'd live with her and nurse her 'heathen'; but if she doesn't go back to 'Grandview' I don't see how I'm going to—maybe she'll go in for settlement work, tho', she spoke of that once; then I could nurse her 'street kids' for her—which would be very much more to my liking. Oh, I love them, dirty and ragged and 'tough!' The class always said I'd land in a mission kindergarten, but I didn't get there. I guess now I'll nurse them instead, and Martha can teach them—I believe I'll have to suggest it to her. It's time she made a change anyway—those Grandview 'heathens' have had her long enough. Then, maybe, I could be useful for once in my life. I think that more than anything else in the world, I'd like the feeling of being *necessary*.

"I do wish that Blanche would come and take away her pet Madonna. It's positively painful to look at and yet, I can't seem to take my eyes away from it, while I have it here. It's so dreadfully fascinating; just like watching a fire you know all the while that it means death and destruction, and yet you keep on looking. Oh! 'love' never *made* that woman's life, it spoiled it, and that isn't a Christ child that she has in her arms—it's a roguish, mischievous, heartless little Cupid; He has torn the heart right out of her and laughs in high old glee; He's her 'pain' and she is hugging it tight—she just *can't* let it go.

"Queer, I've never before setn any of his pictures. Of all the books and books on art that I've read and studied and 'pored' over, I've never seen anything about Del Sarto, or a copy of any of his pictures; this is the first one I've seen. I must try and see if I can get a history of his life, or something that will tell me about him. I wouldn't be afraid to bet on it, that love spoiled his life, for an artist always paints himself into his pictures. I wonder was *this* the woman's face and he painted it with his soul looking out of her eyes? Beautiful enough, but cold and hard and the eyes and mouth look better, her soul had been betrayed—poor, poor thing.

"No, thank you, Blanche—You can keep your Del Sarto—I'd rather have my own little 'Ferruzz'—She would never spoil any one's life—She's lived and loved and suffered and glorified it all, and the baby is such a dear! Why, you could hold him yourself and feel sure that he would let you know when it was hungry-time, sleep-time and that he'd want to be loved and coddled.

"And I do like my 'Tennessee' awfully well, too; but that doesn't *mean* anything—she is merely a beautiful woman and the baby is sweet and cunning as all little babies are, but well, he isn't a wonderful baby like little ——— for instance. Oh, how I'd like to see her and get hold of her, this very minute! I never saw a baby like Jeanette—she's simply fascinating. I guess she is the one thing that can *absorb* me. I'm 'dead to the world' when I get hold of Jeanette. Fate is just too hard and cruel and tricky for anything, to give Rebecca two such babies and not let me have any. Heigh-ho! It's a funny old world methinks, you never can have anything you want."

When we come to analyze or, perhaps better said, to dovetail the diversities of these four persons that she believes to constitute herself, we find that she and they all have certain things in common. In the first place they all suffer terribly, to use her own language; they all dream a great deal.

No. 1 dreams continuously a jumbled mess of silly things.

No. 2 has hideous dreams.

No. 3 has hideous dreams and dreaming mental states.

No. 4 is not very strongly delineated; she is simply an ideal.

Person No. 1 has the personality of a child who is physically weak and morbidly sensitive, and who is determined to have her own way. This person may be construed to represent the desire or determination of the patient to be treated as a child, and especially to have her own way.

Person No. 2 is an old, weak, sensitive creature who has attributes which she has been told that she should develop—humility, modesty, self-sacrifice, the turning of the other cheek when the one has been smitten. She always gives in after discussion. Obviously this was the phase of her personality to treat, it was susceptible to argument, and it was not stubborn.

Personality No. 3 is the healthy one which is indifferent to existence. This is the one which indicates the real wish to be indifferent to the world's affairs even if the health is all right. She is the one who has a splendid thinking and reasoning

mind. She is the one that knows right from wrong, and good from bad. She is the one that has run the gamut of every human experience; she is the Mona Lisa of her imagination. When she says she has fathomed every emotion and passion, when she reads into her story what Walter Pater read into Mona Lisa, "Here is the head upon which all the ends of the world are come; the eyelids are a little weary, * * * the thoughts and experience of the world have etched and molded there. She is older than the rocks among which she sits; like the vampire, she has been dead many times and learned the secrets of the graves; she has been a diver in deep seas and keeps their fallen day about her * * * ." She is merely trying to convey that she has been subject to every tantalizing emotion by her illness and those who have endeavored to cure her to which a human being can be exposed.

Personality No. 4 is the one which is going to overcome the faults of all the other personalities. She has such qualities that every one loves her. She is the blend of virtue and vice which makes the perfect human being. She is the one who sometimes laughs "right out loud" at the others, at their obstacles (in remaining bedridden), their tenacities, and their puerilities. "She is a glorious creature." In reality it was by identifying (to the patient's satisfaction) this personality with the patient that the first secure steps of her recovery were made.

Her attitude toward her doctor is clearly revealed in her confessions "telling everything"; no one can mitigate her suffering, nothing can appease her misery; not only is she utterly alone, but she is adrift like the hulk of a wrecked ship that has been abandoned and of no service to anyone and a menace to others. She has made Herculean efforts to get well, and failed largely because, like Colenoges, solitary hearted, no love hath she, no understanding friend. Physicians particularly misunderstand her. No one commends her, and this adds to the burden of being misunderstood, maligned and maltreated. She will study to be a nurse when she is well, that her life may be an example to nurses and its conduct a spinning light to the whole world. There seems to be a piece of copy missing here! could she improve upon the quality of the medical profession, but even matrimony and its entailments would go smoothly if she could do as she pleased.

To the unprejudiced who came in contact with her she seemed the apotheosis of self-consciousness. Critical, complaining, ungrateful, encountering nothing that was worthy, and experiencing nothing that was deserving of praise. Complaint, destructive criticism, and ingratitude were her chief characteristics the first few months that she was in the hospital. The most important steps in her reeducation were to convince her that these qualities would have to be replaced before she could hope to recover. How this was accomplished it is very difficult to convey verbally. It need scarcely be said that it is not a subject that goes by hard and fast rules. That it was accomplished, that the results have been lasting, is shown by the permanency of her recovery.

During the weeks and months that an analysis of her mental and emotional make-up were being made, she was subjected to a carefully arranged discipline consisting of the utilization of physical measures for the restoration of her health, and the development of her strength, such as salt rubs, cold packs, massage, electricity, and graduated exercises, first while lying down, then when sitting up, and finally while standing by means of support, such as a rolling crutch. An endeavor was made to keep her in an atmosphere of hope that she would recover and every indication of progress was accentuated and magnified. She was encouraged to believe that because she could stand when supported was in indication that she would be able to stand unsupported as soon as she had regained sufficient strength. Small progress was made during the first few months, and the little that was accomplished in getting her to stand, or to walk while she was in the rolling crutch, her knees splinted to keep them straight, seemed to be undone by each succeeding menstrual period, at which time she appeared to suffer insupportable pain. Dr. J. Clifton Edgar reported that her uterine organs were of the most profoundly infantile type, and that child bearing was beyond the question. The uterus was divulsed. She was given ovarian substances and other animal extracts for a protracted time, but no impression was made upon the dysmenorrhea. After much deliberation, and counsel, we decided to advise ablation of the uterine organs, and this was done. For the subsequent two or three months no effort was made to get her to stand and to walk, but our pedagogical efforts were kept up with renewed vigor.

She was encouraged to identify herself with "Personality No. 4," and assured that though the other three had many desirable characteristics none of them would make a heap of all their winnings and risk it on one turn of pitch and toss, and that in reality their attractions, so alluring at first sight, were not the sterling ones to endure the tedium vitæ.

Aided by Mr. F. W. Ellis, Director of Social Research of the Neurological Institute, we had daily prolonged interviews with her, during which the ideals of life were exposed to her intelligence. Personality No. 2 was argued with and convinced, while No. 1 was disciplined, its misdemeanors winked at and its maturity forecast to be identical with No. 4, that it was in reality a sublimation of No. 3. She was encouraged to believe that she would not take up her bed and walk as if a miracle had happened, but that she would reacquire the capacity to stand and to walk. In conformity with this our first efforts were to get her to stand alone, which were successful about two months after the panhysterectomy.

At the end of four months she was able to leave the hospital. During the latter part of her stay there she walked in the streets, finally unaccompanied, and we felt assured that her improvement would continue at home. Two months after her return home she wrote as follows:

"My one excuse for not writing is that I have not made any marked progress; I have to fight hard to keep from losing ground, just drive myself to all the things that I must do in order to get well. You see I am working hard to prove myself a worthy subject for all the thought and time which you spent on me." In another letter two or three months after: "I am so happy to get my walking thoroughly restored. I am now able to take long walks in the country; I do the housework, make beds and wait on the table, and, in fact, do everything around the house. Last summer I worked in the garden all the season." In her last letter she writes that her townsfolk look upon her as a miracle, which undoubtedly gratifies her vanity.

PSYCHIC THERAPY, CLINICAL PSYCHOLOGY, AND THE LAYMAN INVASION.

By J. VICTOR HABERMAN, A.B., M.D., D.M. (Berlin),

NEW YORK.

INSTRUCTOR IN PSYCHOTHERAPY AT THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, AND ATTENDING PHYSICIAN, PSYCHOLOGY ROOM, VANDERBILT CLINIC

Repeatedly the question is put to me "what are the methods of the psychotherapist who has remained free from the Freudian contagion, and how does his work differ from that of the assuaging analyzers of dreams and complexes?" Or again, the less intellectually elegant—that is, such who have not taken recent psychology courses at the colleges—will ask "Isn't psychotherapy just plain Christian Science?" Or finally, some will say, "Now you know you can't practice psychotherapy on everyone because you can't hypnotize everybody, can you?" Freudism, therefore, or Christian Science, or hypnosis is the connotation in these various minds, a something ostensibly insulate and cultish, and you a member of a "special" class. These questions have been asked of me in different form over and over again by students, physicians, and laymen, and show the very narrow conception of this important subject by our colleagues—and our new confidants, the girl undergraduates and graduates and the Sunday newspapers.

And surely these new confidants are making real headway and must be taken seriously. Who knows how soon they will outrun and outwit us, or possibly set up a new healing sect of their own, for at the girl colleges, seminaries, summer schools and in extension teaching work, courses on Psychoanalysis and the "deeper psychology," "inclusive of hypnosis," "sexual hygiene" and other matters psychic and medical are being given[1] while the medical schools cannot find time to teach aught of the psychologic, not even psychic therapy. In other words—and these are actual facts—young women and young men not students of medicine, nor meaning to become such, are being taught medical, sexual and psycho-clinical matters (all under the guise of the "deeper psychology") matters which after all have strong potential therapeutic possibilities, and which are being utterly neglected by the medical schools whose students hear nothing of clinical psychology or child-psychopathology, and next to nothing of the psychic in therapy. So a recent graduate told me that the course given at her college was "terribly popular," and was well attended, and that no doubt some of the girls "will go in for that sort of work" when they graduate.

Now, there can at least be no denying of the fact that the non-Shakesperian stuff that Freudians tell us dreams are made on is strongly inveigling stuff indeed and that a tolerable dose of it and the "deeper psychology" in a seminary or college course would make it vie with tanglefoot in its lure of attraction. Besides, as the young graduate said, "If it's so, every girl ought to know about those things."—They are learning fast, of that there is no doubt, and psychoanalysis has already become a topic for discussion in the parlor, and at the table—with an occasional interpolation, maybe, of the more recent "twilight sleep," or "Maternity" (now playing).[2]

Such of late has been the rapid spread of medical facts among the laity, especially the unbaked and unwholesome facts; and as to the girl colleges, seminaries, and especially those undergraduates who "will go in for that sort of work," and the other grads who must needs soon seek some remunerative employment, heed for a moment the female invasion of our clinics, of so-called "workers," psychologists, speech-orthopractics, clinical-psychologists, and whatnot! Why the major proportion, if not all, of those looking after abnormal children at our clinics and hospitals are young ladies who have learned to make a Binet-test[3]—though the remarkable fact is that a Binet-test will tell you nothing whatsoever of the abnormality of an abnormal child nor give one the slightest clue to mental evaluation in clinical terms. But the startling thing is not that this Binet-testing, because of its easiness and popularization, has cheapened clinical psychology and degraded it from a dignified major calling (as it is reputed in Europe) to a school-girl pastime, and a procedure to be accommodated somewhere in the back yard of Neurology or Psychiatry, but the progress of these testers into the very heart of our institutions, for that is no longer a mere menace, but an amazing fact, and a physician, though he have specialized training and a record of considerable practice and service is scarcely a match for the newcomer, though she be no physician at all nor specially trained, but who comes with the telling lurch of momentum set going by this latest fadism, and its acceptance by those to whom, evidently, after all, the whole matter is a negligible affair.

But to return to those insisting questions and essay an answer:

[1]In one such course I find that even the psychoses and psychoneuroses are to be taken up. In another "dreams in connection with psychoanalysis." In still another "sexual hygiene, psychoanalysis, hypnosis," etc. The magazines evidently are also beginning to give similar courses. *Good Housekeeping* had an article on psychoanalysis in its February number. In the March number this subject is continued under "Diagnosis by Dreams," in which the *libido* gets an airing. We read under the title that this is "of the utmost importance to mothers and fathers. * * * It is obviously impossible to discuss fully in these pages a subject of this nature; but discerning readers will recognize the dangers here pointed out and the warnings given—and will take care to post themselves more fully."

[2]The topic of Eugenics has already become passé in public gossip, while "Damaged Goods," a moment ago on the lips of everyone, is giving way to newer themes of Brieux.

[3]Since the above was written, my attention has been called to the fact that young men were also engaged in this work, and even such who had medical degrees; and that if there be any reproach it falls to the door of the physicians who indulge and publicly proclaim this sort of thing. And the following was pointed out to me: In a half dozen newspapers recently there appeared the announcement, supposedly, of the opening of a certain school for atypical children—in reality, however, apparently so, the press notice of certain physicians connected with the school. Here again was stated that each child gets a Binet test, and that through this cases of abnormal development were discovered, etc. This, of course, is the rankest nonsense, and flaunting it before the public, in keeping with the kind of medical advertising which, in the hands of the Freudian propagandists and these Binet testing "experts" (what a catastrophe would occur if the Carnegie Foundation were to investigate our so-called "specialists" of to-day as it did medical schools some time ago!), has reached the high-water mark of efficiency. This kind of *press-noticing* is the source of the pseudo-enlightenment and bemuddlement of the public and a hoax to physicians themselves. The criticism of my paragraph above, I am sorry to say, is therefore justified. "Old Dr. Gindle" is no longer a G-U specialist; he is to be found among the neurologists, and especially those of the Freudian and Binet-expert types—and alas! not so much among the free lancers as among those connected with some of our best institutions.

One has symptoms and back ground tendencies (inherited or acquired) to treat, and possibly an individual with ultra-moods-feelings-affects and unauspicious life viewpoints to administer to.[4] Symptoms must be cured first—it is for that the patient seeks our aid—and this is probably best accomplished by suggestion in its various forms. It may be the suggestion of word or of such substitutes[5] as electricity, massage, exercise, manual-work, thermic-light, drugs, etc.—which frequently suffice. Or the more potent form of suggestion, namely, hypnosis, may be employed. Freud himself formerly used hypnosis in his own work, and many of his followers still continue to do so. It was the method of the great Nancy school, where the scientific psychotherapy of modern times was inaugurated, nurtured, and first taught. And where deftly applied, it is perhaps the surest and most rapid way of nullifying psychogenic symptoms known to us to-day. Yet that does not make hypnosis synonymous with psychotherapy. It is merely *one* of the psychic methods, and in trained hands, useful, safe, and potent.

There is much misapprehension concerning this method among physicians, many of whom think that by hypnosis one induces unconsciousness, and then forces ideas upon the mind as one might mold or impress wax. Nothing could be less true—just as nothing could be less true than the old superstition kept alive by stage performers of the subjugation and weakening of will, and of the "power" exerted over the patient.[6] Think first of all of the great and inherent calming effect of hypnosis. If it had no other value whatsoever than the deep mental and physical quiescence attained at each induction, with the *tendency* given to continued calm, this would be its own excuse for being. Hence its value in instilling composure in the minds of the high-strung neurotic or the obsessed. In the neurasthenic Geijerstam pointed out that a brief seance proved far more easing and refreshing than several hours of sleep.[7] It is not a state of subjugation, nor of unconsciousness, nor even of subconsciousness, but one of peculiar neuropsychic inactivity and tranquillity. Even where not attained, though attempted, the mental placidity produced soothes and allays the anxious patient, and serves an excellent therapeutic end.

The second equally great value of hypnosis lies in the hypersuggestibility momentarily induced, so that one's "logic" will here take root and ripen (post-hypnotic suggestion), where in the waking state the veriest fineness of logic with such patients at times proves unavailing. One does not proceed as on the stage, "now your nose is of rubber," whereupon the subject draws out his hallucinated elastic proboscis and goes through antics of delight. One reasons and enjoins in the same rational way, and infuses *conviction* precisely as in the waking state. It might be remembered, too, that in this condition the field of memory may be widened, that is, the associational play be more unconstrained, be deeper and more agile (though the contrary may also be the case), and a patient may tell you much that does not occur to him in the normal state. Even Freud used hypnosis for this purpose, thinking he got to subconscious material in this way.

The hypersuggestibility gives easy reception to your word, and symptoms rapidly, often at once, disappear. Now, why "analyze" a symptom for several months if you can dissipate the same in a few minutes, or a few visits? Does one think it will recur more readily if suggested away than if analyzed away?[8] It makes absolutely no difference what started such a symptom, or habit, a tremor, a tic-movement, a stuttering, etc.; once become a habit the causating impulse must be obviated, or sidetracked, or counter-impulsed. *Learning* the cause does not in itself make such symptoms, etc., disappear—cannot in fact influence it in the slightest, unless one again employs suggestion saying "now that we have hit upon the cause, the trouble will disappear." Or again, if a patient has his attention and expectancy keyed up to their highest during an analysis, and is told directly one comes to the "causative psychic trauma" the symptom will disappear, of course it may disappear, and this very intense suggestive procedure is in large measure the reason for the success of psychoanalysis when it succeeds.[9] (Dubois).

How one can little by little "bend" the background tendencies and so change a pathological "disposition" by suggestion, more slowly in the waking, more rapidly in the hypersuggestible hypnotic state, is evident. And in this social world of ours more individuals are stirred and affected by the influence of others working suggestibly upon them than by any other or all other methods combined. This is

[4] It must not for a moment be forgot that one has to think of the physical and physiological of the individual as also acting upon the mind, as well as the mental *reaction* upon the body—and the further continued interplay of one upon the other. Only he is a good psychopathologist and psychotherapist who is a thorough all-round physician. And he who in his enthusiasm for the psychic forgets or ignores the other branches of medical science, becomes an unsafe or even dangerous fadist.

[5] These substitutes, of course, have other effects beside the suggestive; but the suggestive element may be made most powerful.

[6] Aschaffenburg writes (in Curschmann's "Lehrbuch der Nervenkranheiten," p. 796), "The fable that hypnosis paralyzes the energy of the patient still more, can only be seriously held by one who has never tested hypnosis. I am assured that many people on whom all methods of treatment were tried without effect, finally and only regained their vitality (Lebensenergie) through hypnosis." Interesting are also the words of Friedländer on this point, who said: "Den Wert der Hypnose sehe ich nicht allein in den sinnfälligen Erfolgen, sondern mindestens ebenso in der durch sie ermöglichten dauernden Beeinflussung des Seelenlebens, *in der Selbsterziehung, Eigenkontrolle, Konzentrationsfähigkeit, Willenstärkung*, nachdem der Arzt vom Schauplatze abgetreten ist."—*Jahresversam. der Gesellschaft Deutscher Nervenärzte*, Frankfurt, Oct., 1911. See also the present writer's study of Hypnosis, *Internal. Clinics*, Vol. IV, Series 10.

[7] *Zeit. f. Psychotherapie und med. Psychologie*, Bd. III, Heft. 5 & 6.

[8] Freud himself has written ("Studien über Hysterie," 2nd edit., 1909, p. 14): "Of course we do not cure the hysteria; inasmuch as it is constitutional we can do nothing to effect the recurrence of hypnoid conditions. Nor can our methods during the productive stages of an acute hysteria keep new symptoms from appearing and taking the place of those made to disappear with such great pains and difficulty." Again, p. 228, "It (the cathartic method) does not affect the causal conditions of hysteria, cannot therefore inhibit the occurrence of new symptoms on the ground of the dislodged ones."

[9] One must remember there is the added factor of "belief" in the physician, one of the strongest of psychotherapeutic factors. (Ziehen). This belief is increased by the fame of a physician, or by the knowledge of his *having cured* cases "just like" that of the patient. We try to increase it by our manner, by the care and thoroughness with which we examine the patient, and finally by the firmness with which we express ourselves. Of greatest importance in getting a patient to believe in us (as Dubois has pointed out) is belief in ourselves and our work.

the great impellant of the stage, the book, the example seen or heard of, and in largest measure of news that is read.

But suggestion is by no means all, is in fact only the minor part of our psychotherapy, just as we may term minor adjuvents to treatment our counselling the patient to avoid fatigue and irritability, or those factors (scenes, people, environments, etc.) which prove sources of irritability, of disphoria, or of affect-explosions: (change of environment may however be of the greatest importance in the treatment of cases, especially in children); or as we divert attention by giving manual occupation or study, or add hydrotherapy, feed up, tone up,[10] attend to elimination, etc., all of which also act forcibly upon the mind, or prescribe "will gymnastics" to counteract idea-habits and abnormal impulses. The symptoms once cured, one must strengthen the resistance of the patient so that he becomes equal to the task of coping with his life conditions—so that symptoms do not reoccur. One must induce in him a "philosophy" which will place him above his maladies or shortcomings, for all time, or until he outgrows his psychopathies, so that he himself grasps the helm, knows how to keep within latitude of his own limitations, and learns to clear the reefs of "affective" excesses, upon which many a psychopath has rasped and gone to splinters.

But just here one will be asked by those leaning to the Freudian, how will you learn that patient's inherited trends or such acquired by fallacious training or "affective" conflict or accident; how get to know the coloring of his subjectivity, that which characterizes the background disposition of the man, and so his false evaluations of and maladjustments to life? How will you ferret out the causes of his psychopathy or come upon those so-called complexes which, without his knowing (supposedly so), lead him emotionally or ideationally astray?[11]

Let it be remembered (the Freudian movement seems to have driven it completely out of the minds of physicians) that every psychotherapist and probably every psychiatrist worthy of the name, analyzes the mental make-up of his patient and probes by judicious questioning his life story with its domestic, social, sexual, and other trends and thus endeavors to understand his patient and his reactionism, and tries to unravel his psychopathy and come to its underlying causes when possible.[12] I have spoken of this method as *anamnestic analysis* (ὀνάμνηστος, *i.e.* that is remembered, that can be recalled to mind) to differentiate it from that psycho-(sexual-) analysis which does not honestly bring out the memories of the patient, but suggestively interprets *into* the mind and distorts data by subjective "translation" so that the resulting story is fundamentally out of the physician's mind, not the patient's.[13]

As I have already intimated, such analysis has always been essayed by psychiatrists and neurologists. To aid in the work various psychologic methods were evolved, especially the association tests of Kraepelin, Ziehen and their students (so especially the studies of Aschaffenburg, Levi-Soul, Isserlin, etc.), also kymographic e-motor registrations, like those of Sommer, the plethismographic tests, the psychogalvanometer tests of Veraguth, etc. We might speak of all these as psychological aids (psychological analysis) to a better comprehension and evaluation of the patient's present state of mind by understanding the nature of its associations. Along these lines an immense amount of work has been done by Kraepelin, Ziehen, Sommer, Bechterew, etc., all using strictly scientific methods to the exclusion of metaphysics and fantasy. That headway is being made but very slowly with such psychologic methods is only too true; the subject, however, is just in its infancy, and phychology itself has as yet given scant aid.

This is not the place to go into the matter at greater length. Let it suffice to state that by means of *anamnestic analysis* one may gain as deep an insight into the personality of an individual and his mental environment as with the rational methods at our command today this is actually and veritably possible. Together with the physician's receptive attitude and guiding counsel, it proves the strongest weapon in our psychotherapeutic armamentorium. Through this the patient attains an immense relief by the unburdening of himself—the affiance of the confessional, as it were, for surely the physician admitted to the full confidence of his patient becomes the most intimate of confessors—gets a kind of start in the regeneration of his self-reliance by feeling he has found a helping, compassionating friend, who "understands," who will assist in the allaying of the obtaining difficulties, of whatever nature they be, realizes an immediate gain in the advice received as to how to obviate these difficulties or meet them, should there be such, and above all, in the cogent insinuations to enter the path of right living and right thinking, by maintaining calm and restraint, by emboldening his spirit to be master, not mastered by fate, by inviting an attitude of hope and expectation (so absolutely necessary in the cure of the nervous and

[10]A patient who is in bad physical condition is a very poor subject for psychotherapy and must first be "built up."

[11]The supposition that one must know all this in order to cure a patient is an affectation. The assumption that one *does* learn all this about every patient is likewise an affectation—one doesn't and still cures him. We have been told that not all but certain cases only are suited for psychoanalysis—those young enough, intelligent enough, co-operative enough, and having money enough to afford such a treatment. (Clinic patients do not seem to have the qualifications either—it being but rarely if ever tried on them.) How are the remaining cases treated? The Freudian doesn't say much about it. Can they not be cured, or only their symptoms? Or is some other method then to be tried—which?

[12]At the present state of development of our science it is not the usual but rather the unusual thing to come upon the underlying causes in the psychoses. Even in the psychoneuroses one remains quite as often in darkness. We have not made much advance in *results* even though considerable has been done to advance methods. When writers, as one recently in the *N. Y. S. Journal*, talk about our having recognized the psychogenetic mechanism underlying Dementia Præcox, or, as another stated, that Jung has given us the key to this psychosis, or where anyone says psychoanalysis has cleared up any of the psychoses, they state utterly untrue facts. The great psychiatrists of Europe have not found that psychoanalysis has aided psychiatry at all (Kraepelin, Ziehen, Hoche, Anton, Sommer, Aschaffenburg, Isserlin, etc.). Through these methods some of these mechanisms *may* in time be made clearer, *maybe;* as yet *nothing* has really been cleared up. It is almost dumbfounding how these things are continuously repeated in journals until everyone takes up the delusion and accepts it without a doubt. Even Bleuler now only goes so far as to say of psychoanalysis that "it represents an *experiment* out of which one may often infer correctly certain definite psychic processes," etc.—*Jahresver. Deut. Ver. f. Psych.* at Breslau, May, 1913.

[13]See the author's "Some Recent Criticisms of Psychoanalysis," *Med. Rev. of Rev.*, October, 1912; "The Psychoanalytic Delusion," MEDICAL RECORD, September 6, 1913; "A Criticism of Psychoanalysis," *Journal of Abn. Psych.*, October-November, 1914.

neurotic)—and the final awakening of joy with its salutary stimulations because of the encountered relief and renewed faith—again reclaims trust in himself—that iron string to which every heart must vibrate, as Emerson has said, for after all "nothing can bring you peace but yourself."

This, then, is real psychotherapy, and is the method we have tried to employ and encourage as fully as time would permit, in our own psychotherapeutic clinic—and with the most gratifying results. Here you have suggestion, persuasion and re-education compounded and raised to their highest potence, and in the sincere practice of such one shall find the physician ennobled to that superlative stage of the healing art where he may verily be deemed as the Germans term it, *Seelen Arzt*—soul-physician.

But this does not complete the story of psychotherapy. Its most consequential chapter, that dealing with the prophylaxis and early assuagement or eradication of half the ills that humanity is burdened with, must still be factually written. At some future time when possibly physicians have awakened to the seriousness of judging the child's neuro-psychic abnormalities as important as that of its intestines, or lungs,—often indeed as portentous in its incipience as the first gray tubercle intrenched in those lungs—when the school authorities shall have been shocked out of their long years' sleep, and ask the why and wherefore of the six or seven million retarded children in this country, and apply to us—or those laymen invaders who may by that time have long since displaced us—for a diagnosis, a prophylaxis and a therapy, when the civic and state authorities come to realize the immense gravity of the fact that here lies germinant the whole problem of the psychopathic constitution and here and probably here only, therefore, the source to be reached of those contaminations of society, delinquency, prostitution and in largest measure of criminality and insanity, and that at this source, and this source only, shall one ever be able to dredge out the pollution and lessen the hordes of human derelicts and decrease the millions in expenditures used and misused in finally housing and maintaining them—possibly then, at that belated time, the work begun by Ziehen abroad may come to leaven, and the universities have departments devoted to the careful study, examination and analysis of abnormal children and the neuropsychic abnormalities of normal ones, and in close association the means of treating, training and coercing by psychic urgence their abnormal mental functioning into normal paths—and this not in the hands of men just graduated from their medical school, or untrained girl workers who are neither physicians nor psychopathologists, or indeed physicians and so-called "experts" whose chief qualification lies in their having had ample advertisement on several occasions in the Sunday papers, but under the direction of those competent and qualified and pursuing this work as a momentous and serious calling.

Varicella with Two Eruptive Stages and Accompanying Erythema.—O. Silberknopf reports the case of a seven-year old girl in whom an attack of varicella was marked by the appearance of the eruption in two main crops separated by an interval of eight days, during which there was observed a widespread erythema on the trunk and extremities.—*Zentralblatt für Kinderheilkunde.*

INDICATIONS FOR TREATMENT OF HEART DISEASES.*

By Robert Abrahams, M.D.,

New York.

Adjunct Professor of Medicine and Adjunct Visiting Physician in the New York Post-Graduate Medical School and Hospital; Consulting Physician to the Manhattan State Hospital and the Home of the Daughters of Jacob.

Every physician who examines an abnormal heart must hold before the mirror of his mind two truisms: First, not every diseased heart needs treatment; second, not to regard the murmur as

"The rift within the lute
Which soon shall make the music mute."

This idea may be further developed by stating a broad and comprehensive principle in the treatment of heart disease, namely, that signs which mark the presence of disease do not indicate the necessity of treatment; symptoms which are the expressions of the failing functions of the weakening heart are the sole and sure indications of treatment. The question, therefore, at once arises: which are the symptoms and what are the indications? Serially they are as follows:

1. Dyspnea.—Cardiac dyspnea is a dyspnea of exertion. If a patient gets out of breath after walking a short distance, or by going up a flight of sairs, or by bending to take his shoes off, or by any slight exercise, the patient's heart needs treatment. Such a patient, in all probability, has mitral disease with beginning failure of compensation.

2. Cyanosis.—This symptom, like the preceding one, is produced by exertion; it disappears after rest, and it indicates a failing heart and, most likely, a lesion of the mitral valves.

3. Edema.—Edema resulting from heart disease is an ascending edema; its appearance around the toes or ankles is an indication of commencing decompensation.

4. Cough.—The "heart cough" may be dry and harassing, may become spasmodic on exertion, or it may be attended by mucous expectoration. "It is due to the congestion of the bronchial veins and is a serous oozing from the venules." This cough denotes failure of both right and left hearts and calls loudly for treatment. The heart cough occurs most often in mitral disorders.

5. Enlargement of the Liver.—In many cases of failing heart, the border of the liver extends down to a line with the umbilicus. This denotes hypertrophy; the hypertrophy results from congestion; the congestion is produced by a failing heart which hinders and interferes with the portal circulation. It is to be noted, and perhaps remembered, that in some instances the enlargement of the liver is the first and only indication of cardiac failure. (I have seen and known this pure hepatic congestion to be mistaken for cirrhosis, although very prolonged congestion may actually lead to cirrhosis of that organ.)

6. Anemia.—Anemia which does not yield to treatment but which, on the contrary, defies treatment, indicates a failing heart, a heart that cries for treatment. Anemia of this nature points to aortic disease.

7. Hemoptysis.—Raising of blood in small or in large quantities not infrequently occurs as an early sign of heart failure, and as such it constitutes an

*Read by invitation before the East New York Medical Society, December, 1914 and the Bronx Medical Society, March 10, 1915.

indication for treatment. Hemoptysis is an incident of mitral trouble. The blood finds its way into the lungs in different forms. One form constitutes pulmonary apoplexy, which, according to Rokitansky, "is very frequently found to be associated with active dilatation of the right heart and it seems to bear the same pathogenic relation to the cardiac affection as cerebral apoplexy bears to active dilatation of the left side of the heart."

8. Vertigo.—Vertigo, in the presence of aortic disease, means poor compensation calling for attention.

9. Insomnia.—Sleeplessness, restlessness, and nightmares appearing in aortic insufficiency indicate broken compensation, necessitating therapeutic help.

10. Dilatation.—Cardiac dilatation resulting from valvular or structural defect embraces all indications, those that were mentioned and a few which are omitted, because it gives rise to all symptoms, singly or combined.

Treatment.—The treatment of disease of the heart is bound up with, and is a part and parcel of, the history of digitalis. William Withering, a Birmingham practitioner, gave his "Account of Foxglove" in 1785. Since then no writer has penned a line on the management of cardiac affections without mentioning this epoch-making drug. Whatever methods and measures are employed in the treatment of lesions of the heart, digitalis is used at one time or another and in one form or another. It is the equal of mercury in syphilis and quinine in malaria, and he who knows the use and abuse of digitalis is competent to treat diseases of the heart.

In approaching the subject of treatment, the natural inclination is to follow the etiological factors of the different types of diseases of the heart. This would be extremely advantageous provided one could inform oneself on the causation of every heart lesion which comes up for treatment. This may be possible in the future, although an attempt can be made in the present.

Syphilis and rheumatism are the two prevailing agents in the production of heart disease. Both affect the muscle and both destroy the valves. Some differences exist between these two mischief makers which it may be well to mention and important to bear in mind. Rheumatism frequently produces acute endocarditis, while syphilis very seldom does. [illegible] fers to lay hands on the valves, [illegible] kes to damage the musculature. [illegible] ws a predilection for the mitral apsyphilis is attracted by the aortic system of valves. Armed with such clinical data concerning the etiology of some lesions of the heart, an attempt to capture and destroy the causative enemy is not only mandatory but may prove highly successful.

Spurred on by modern methods of diagnosis and impressed with their great value, we should avail ourselves of laboratory assistance, namely, the Wassermann test and blood culture. The latter should constitute an essential element in the examination of a patient who suffers from acute or subacute endocarditis coming and going at shorter or longer intervals. A blood culture may result in the discovery of the *Streptococcus viridans,* and then the treatment can be specific, either autogenous vaccine or autoserum intravenously.

Again a proper study of all heart lesions is not complete, both from the standpoint of etiology and treatment, unless, and until, a careful search has been made for small pockets of pus stored and hidden in some nook or corner of the complex machinery of the human body, principally, however, the mouth and anus. It is neither a subject for laughter nor matter of skepticism to read that the removal of the appendix resulted in the cure of an obstinate trigeminal neuralgia. We rather should stand in amazement at the evidence connecting ulcer of the stomach with a few drops of pus under a tooth, and admire the man who traced the connection. That endocardidtis, valvulitis, and arthritis are due to *Streptococcus viridans* found in purulent and spongy gums, I have not the least doubt. Neither have you. Now, here is a fruitful indication for treatment and prophylaxis of heart disease. In search for the enemy, one should not stop at the gums, but stray lower where the tonsils grow. The tonsil, like the appendix, was born to make trouble. Scrutinize it; if necessary use a searchlight; examine its secretion and perhaps luck will crown your efforts. The comparison of the tonsil to the appendix is not far-fetched. What the appendix is to the peritoneum, the tonsil is to the endocardium. Many and many a case of endocardial disease can justly be laid at the door of the tonsil. In the treatment of cardiac disease associated with attacks of tonsillitis, the pesky organs must either be ablated or else frequently bathed with a solution of permanganate of potassium 1/5,000. This is the best antiseptic for that purpose and its employment should be considered part of the daily toilet.

If syphilis be found to be the etiological factor (80 per cent. is the accepted frequency of this infection in aortic disease), then mercury is the redeeming drug, the sheet anchor; mercury by inunction. The iodides are of little value even in the face of arteriosclerosis and high blood pressure. Salvarsan is permissible and at times desirable, rarely, however, urgent. A syphilitic heart stands salvarsan very well. After the salvarsan, one rubbing of five grams of blue ointment should be made every day for fifty days in succession.

This method of treatment is indicated in cases of aortic disease even in the face of a negative Wassermann reaction at the beginning of the treatment. The Wassermann may become positive during the treatment. It is a waste of time to wait for the autopsy to confirm the diagnosis of syphilis. No patient was ever benefited by autopsy findings. Action must sometimes be taken on the flimsiest suspicion, for syphilis is a disease of the hovel and the palace, of the sanctum and the saloon, of the wise and of the foolish, of the innocent and the guilty.

These considerations make it evident that the ideal treatment of heart disease rests in finding and removing the cause. But is this ideal attainable? It must be admitted that, excepting in particular instances, it is not, for the reason that the present status of our knowledge of etiological agents is still hazy, nebulous, uncertain. Besides, even in the case of lesions which are known definitely to have been produced by spirochetes or streptococci or any other of the multifarious denizens of the microscopic world, if such lesions remain unrecognized and specifically untreated for a long time, specific therapy subsequently applied will not cure them. Changes which were wrought in the valves will persist, and changes which have occurred in the muscle of the heart will remain, notwithstanding the application of specific remedies. Etiological treatment may, and does ameliorate, in these late and distressing cases, annoying symptoms; it may also

for a time stay the downward march of destruction of tissue, but sooner or later the diseased organ has to be considered and treated, from the standpoint of *functional* derangement.

To such consideration I invite your attention for the next few minutes.

Valvular lesions constitute the great majority of cardiac affections; it is fitting, therefore, to take them up first for consideration. To treat a valvular lesion intelligently, or to permit it to go without treatment, also intelligently, one must know the stage of the lesion which is present at the time of the examination.

Mitral insufficiency being the most common lesion, it merits first attention. There are three stages of mitral insufficiency. The first stage is characterized by one sign, and that is a systolic murmur which is heard over the apex and is limited to it. This murmur, in the absence of other signs of the mitral defect, is frequently mistaken for a hemic murmur. The size of the heart in this stage is normal, and subjective symptoms are conspicuously absent.

The second stage is characterized by the murmur mentioned plus its transmission; displacement of the apex; systolic thrill; hypertrophy and dilatation; accentuation of the second pulmonic sound and diminished pulses (90 per cent.) when taken while the arms are held in an upright position. Subjective phenomena may or may not be present in this stage.

The third stage embraces all the physical signs of the second stage with the addition of edema, anasarca, dyspnea or orthopnea, cyanosis, bronchorrhea, insomnia, etc., that is to say, symptoms as well as signs.

Mitral stenosis has but two stages, the bad and the worse.

The first stage is characterized by a presystolic thrill or presystolic murmur, sometimes one, sometimes the other, occasionally both; accentuation of the second pulmonic sound and a diminution of the pulses in the arms raised above the head. There may or may not be symptoms present at this stage of the disease.

The second stage is characterized by all the signs of the first stage, including distressing symptoms, such as dyspnea, cyanosis, tachycardia, harassing cough, dropsical effusions, "sinking spells," etc. The condition known as auricular fibrillation is frequently associated with the third stage of insufficiency and the second stage of stenosis of the mitral valves. When this condition occurs, then the whole gamut of arrhythmia becomes a noted and notable feature of the valvular affection. The distress and annoyance resulting from this cardiac irregularity are added to the long list of subjective misery.

Three stages are assigned to aortic insufficiency.

The first stage is indicated by the diastolic murmur.

The second stage has the murmur, but it also has displacement of the apex, hyperthophy, Corrigan pulse, increased pulsations of carotid and other superficial arteries and capillary pulsations. The interval between the first and second stages in this disease is comparatively brief.

The third stage embraces all the physical signs of the preceding stages plus anemia, vertigo, anginal pains, insomnia and nightmares, dyspnea, edema, and dropsical effusions in membraneous cavities, all these form the closing and terminal incidents of this serious cardiac trouble.

Aortic stenosis has no stages. This disease is always benign. When the perfect hypertrophy which is typical of aortic obstruction yields to dilatation, then the lease on life becomes extremely short, regardless of any form of treatment.

The division of valvular disease into stages and a thorough appreciation of the signs of each stage is the most useful thing in treatment, to say nothing of the moral and intellectual satisfaction one derives from accurate knowledge and information.

There can be no objection to such a division. Tuberculosis is divided into three stages, although at times one finds all stages in the lungs. Yet the division is very useful. Pneumonia is divided into stages, so is cholera, so is smallpox, so is bigpox, syphilis. I advocate the division of arteriosclerosis into three stages—a very helpful division.

The purpose of presenting the treatment of chronic heart disease may be better fulfilled by taking up concrete, though hypothetical cases, one after another, beginning with the simplest and ending with the complex, as they appear in each separate lesion.

Mitral Insufficiency.—Case I.—Physical examination discloses a systolic murmur at the apex. No other sign present. Symptoms are absent. Diagnosis, mitral insufficiency in the first stage. A case like this imperatively forbids the use of cardiac drugs. It may need an antirheumatic remedy if there be pain in the joints; it may need iron if there be anemia, or, most often, the mixture of rhubarb and soda supplies all the necessary medication. The very important points to remember in a case like this are: First, not to get alarmed over the murmur and in consequence belabor the heart with digitalis, and, second, not to tell the patient that he has a "weak" heart and thus throw him into unnecessary anguish.

Case II.—Physical examination discloses a systolic murmur at the apex, a systolic thrill, apical displacement, accentuation of the second pulmonic sound, and some enlargement. Diagnosis, mitral regurgitation in the second stage. However, no symptoms are present, which signifies that there is no indication for treating the heart. The latter is a guarantee that compensation is perfect.

Now, though the diagnosis is unmistakable, yet the treatment should not be directed toward the heart. As in the preceding case, one must allay rheumatic pains if they are present; for that purpose there is nothing better than novaspirin gr. x, *t.i.d.*; anemia may be more perceptible in this stage, then iron, either in the form of Blaud's mass, gr. v, *t.i.d.*, or the aromatic tincture of iron of Atthensteadt ℥ss., *t.i.d.* This patient will be constipated so that a saline or other cathartic once or twice a day will be called for.

Should there be any of the above-mentioned indications for treating the diseased heart, such, for example, as dyspnea or cyanosis, or edema of the ankles, then the patient is put to bed. Rest in bed is the best restorative for a failing heart. Rest in bed frequently dispenses with cardiac drugs. However, should the patient refuse to go to bed, or should rest in bed prove inadequate, resort must be had to a cardiac tonic. The best cardiac tonic in mitral regurgitation with broken compensation is digitalis. Twenty minims of the tincture or a half ounce of a good reliable infusion three times a day will accomplish the desired result. This dose of digitalis must be kept up until the signs of decompensation have disappeared or considerably abated.

After that the dose is reduced to half and continued, with few intervals of interruption, indefinitely.

Case III.—Physical examination reveals all the signs of the valvular disease plus the sequelæ of a dilated, maybe degenerated, failing heart. In this instance the patient has no other choice but to go to bed. The best posture is, perhaps, the semi-recumbent, because the dyspnea may be intense. This posture is better borne by the patient. Treatment is begun with one grain of calomel in divided doses followed, shortly after, by a saline laxative. As soon as possible one drachm of the tincture of digitalis should be administered; then wait twelve hours, at the end of which time, if there is no improvement in the dyspnea or cyanosis, another drachm is given. The next day the dose of the tincture is to be reduced to half drachm. This reduced dose is kept up for three days and is then further reduced to twenty minims. The last is to be continued indefinitely, save for a short interruption, here and there. In case the dyspnea is very severe, prompt relief may be obtained by a subcutaneous injection of 1 6-¼ gr. of morphine.

A physician who prefers the infusion to the tincture must begin with one ounce at least three times a day until symptoms of failure improve, and thereafter administer it in smaller doses—half ounce *t.i.d.*

Aortic Insufficiency.—Case I.—A patient with a diastolic murmur but with no other sign. The well-known pulse of this disease is little in evidence, because in the first stage of this valvular defect the incompetency of the valves may only be partial to produce the collapse of the arteries through the regurgitation, and the left ventricle is not hypertrophied enough, if there is any hypertrophy at all at this stage of the process, to produce the strong impact, the vigorous jerk of the palpated artery that is so marked in an advanced second stage. There will be an absence of all symptoms pointing to any functional disturbance. The heart in this stage needs no treatment. Any one of the cardiac drugs will disturb it. In this condition as well as all through the life of the patient iron is indicated and should be given. From what was said above regarding the syphilitic origin of aortic disease, specific treatment should be instituted as outlined in the early part of this paper.

Case II.—In this case we will presume that all the physical signs of aortic incompetency are present, namely, diastolic murmur, diastolic thrill (rare), marked hypertrophy of the left heart, throbbing arteries, and pulsating capillaries. This condition indicates the second stage of aortic insufficiency. Although we have in this stage all the signs of complete destruction of the aortic valves, yet in the absence of symptoms, that is, indications of functional disturbance, no form of cardiac remedies should be directed to the heart except antiluetic measures—the latter used empirically if no positive Wassermann is present, and in good faith if the test is positive.

On the other hand, if one or two of the above mentioned indications are present, one must resort to rest in bed, if possible, and the administration of cardiac drugs. Here, again, the best is digitalis. But digitalis in aortic insufficiency has to be given cautiously, judiciously, and intelligently. The initial dose should be five minims three times, the first day; the second day, five, six, five; the third day, six, seven, six, and so on until a dose of twenty minims three times a day is reached. After that, one begins to reduce the daily dose by one minim until the initial dose is reached. This dose is continued indefinitely, or until a contraindication to digitalis arises. The most important contraindication is intermittence of heart action. Look out for that.

Case III.—We suppose that the patient has all the signs and nearly all the symptoms, that is to say, the patient is in the third or terminal stage of the disease. The problem involved in the treatment is extraordinarily difficult. Antisyphilitic treatment is of little or no avail here, even if the diagnosis of syphilis is certain. There is more than one difficulty to overcome: first, the heart muscle is disorganized; second, the excessive dilatation of the ventricles and their openings produces relative insufficiency of other than the aortic valves. Digitalis is still of service, and larger doses can be ventured on account of the added valvular incompetencies. Either the tincture or the infusion may be used. One of the comparatively recent preparations of digitalis acts admirably in a case like the one under consideration. I refer to digipuratum. Digipuratum has gained the confidence of scores of students of cardiac pathology. It can be given with perfect safety in many diseases of the heart. In aortic regurgitation, digipuratum has hardly a peer. If this preparation keeps up its pristine purity, it may, by a still better knowledge of its action and reduction in its expense, become the first and foremost member of the digitalis family. Digipuratum can be given in tablets, one every four or six hours, or in solution by mouth or under the skin. Ampules are prepared for the subcutaneous administration. One injection a day is usually enough.

The second best drug in a case of this gravity is morphine by mouth or hypodermically, preferably the latter, from 1/6-1/4 grain. There need be no childish fear of establishing the habit. The third drug is strophanthin intravenously, 1/100 gr.

Mitral Stenosis.—Case I.—The patient has a presystolic murmur or a presystolic thrill; accentuation of pulmonic second sound and the pulse phenomenon mentioned above. These signs constitute the first stage of the disease and they may be associated with no symptoms indicating necessity for treatment. This condition, however, is very rare in mitral stenosis. The interference in the circulation brought about by the obstruction causes early disturbance of the heart's action. There may be attacks of palpitation, or attacks of dypnea, or attacks of spasmodic coughing. Either one constitutes a justification for treating the heart. Here, as in lesions of the heart, where direct cardiac therapy is indicated, rest in bed is desirable. If such rest cannot be secured, or if in spite of rest the annoying symptom persists, then one of two drugs should be given, to wit: caffeine sodium benzoate gr.v. *t.i.d.*, or tincture of strophanthus ♏v. *t.i.d.* I prefer the former, only one must see to it that the last dose is taken early in the evening. If taken late in the night it interferes with sleep, and sleep is important in a disease which promotes insomnia.

No digitalis should be given, as I am absolutely convinced that digitalis aggravates this stage of mitral stenosis. It is often hard to explain this incompatibility between first stage mitral stenosis and foxglove, but the incompatibility exists nevertheless, and it is prudent to recognize it and respect it.

Case II.—Here is a patient who shows all the physical signs of mitral stenosis plus distressing

symptoms of dyspnea, cough, edema, and rapid heart. The rapid heart is irregular in action, showing premature contractions and intermittence. This heart is failing, its auricles are in a state of fibrillation. Treatment consists of rest in bed and the administration of digitalis. Digitalis is indicated because the heart is dilated and decompensated, also because auricular fibrillation yields to the drug and the larger the dose the quicker the result. The dose of the tincture is from 30-40 minims three times a day until the patient is relieved. Relief is indicated by a reduction in the pulse rate and a diminution in the extra systoles. Calomel, iron, and some cathartic are as useful in stenosis as they are in insufficiency. This case may need a dose of bromide in the evening because the patient is restless on account of the riotous action of the heart.

Aortic Stenosis.—Unless this valvular disease is caused by syphilis it requires no treatment. It does not call for treatment until the perfect hypertrophy which invariably attends the heart in this lesion yields to dilatation. When that occurs, it matters little what you do.

Myocarditis is tabooed by some writers and clinicians. Cardiologists who are imbued with the latest researches and discoveries of the heart, bearing upon its anatomy and physiology, have relegated "myocarditis" to the dark ages of cardiac pathology. I heard it said the other evening that myocarditis as a disease does not merit the paper that it is printed on.

However, be that as it may, I insist, even at the risk of being considered a fossil, upon the continuance of that disease as a clinical entity, revealed in many forms and in varied though dismal colors—once it is extra systole, once auricular fibrillation, now heart block or one of the many pictures of so-called cardioneurosis.

Given a patient of middle age with or without arteriosclerosis, but with an irregularly contracting heart; dilatation with no murmur; feeble sounds; shortness of breath; enlarged liver; sallow skin and yellow conjunctiva and sclera, this patient is a victim of chronic myocarditis—the opinion of ultra modernists to the contrary notwithstanding.

The treatment consists in absolute rest in bed for a fairly long period and the use of digitalis. The interdiction of digitalis in chronic myocarditis is one of the barnacles of medicine comparable to the fallacy of the "cumulative effects" of the same venerable and venerated drug.

Diet in chronic heart disease, valvular or structural, is a matter of personal judgment and conviction. The wise and the courageous will put few restrictions on diet; the foolish and the timid will reduce the patient to a fluid diet and thus successfully subject the poor sufferer to starvation. Cut out bad habits like liquor, coffee, tea, tobacco, and let the others that give sustenance to the body and strength to the weary heart alone. A good principle to bear in mind in connection with diet in all chronic diseases of the heart, and many diseases of other organs, is to mix the diet with brain, just as a famous artist mixed his paint with brain.

The paper is getting too long to include in it the treatment of various sequelæ and associate conditions of heart disease or diseases of other organs or various phenomena seen in the terminal stages of each and every lesion.

My aim and endeavor has been to point the way to correct diagnosis, to indications and definite lines of treatment. I have left much room for individual experience, for individual predilections in drugs, and for attention to details and deviations as may from time to time arise in each case.

A FEW SUGGESTIONS IN HANDLING CASES OF DIABETES MELLITUS.

By HUGO BLUM, M.D.,

NEW YORK.

Since cases of diabetes mellitus are by no means rare in the active practice of the busy physician, he should be equipped for and able to perform all of the simple tests for urine supposed to contain glucose. The practitioner who can depend upon his own skill in making the necessary tests is far better off than the one who is dependent upon a laboratory; not alone in making an almost immediate diagnosis but in the subsequent treatment of the patient. In not a few cases where the nature and progress of the disease demand very frequent urinary examinations, it is most essential that the physician be independent of any laboratory. Where the financial circumstances of the patient forbids the added fee of necessary frequent laboratory analyses, the dependent physician might attempt to compromise by having fewer examinations made than the case demanded, thus interfering with the proper treatment or even endangering life in cases of a severe acidosis. To insist upon the patient paying what he cannot for analyses, and this in cash, would in all probability lose him the case.

For ordinary clinical purpose only two tests need be applied in the qualitative examinations for glucose—Fehling's and Nylander's. In cases where there is any doubt as to the nature of the reducing substance, a third—the fermentation test—must be made. In carrying out Fehling's test only a copper red precipitate should be regarded as of positive diagnostic value; a yellow, green, or greenish-yellow is due to prolonged and excessive boiling, the reduction being caused by the splitting up of conjugate glycuronates. The reaction is ofttimes seen in normal urines; the fermentation test will quickly clear up the doubt, as glycuronic acid will not ferment.

In Nylander's test a dark brown color which changes to an ebony black is of diagnostic value only; where the brown does not change, glucose is not present. It is due to the reducing power of some other substance also forming glycuronates. Saccharin, rhubarb, salicylic acid, camphor, antipyrine, senna, and chloral hydrate are in the main the more important substances which after ingestion have this power. The urine being free from albumin, a necessity for the accurate carrying out of this test, Nylander's will respond to as low a sugar content as 0.1 per cent.

After the presence of glucose has been determined by the foregoing tests, the important process of a quantitative examination is imperative. For this nothing is better or more simple than the method of Rudisch. The solution containing copper sulphate 4.17 gm., sodium sulphite 50.00 gm., and sodium carbonate 80.00 gm. (pure crystallized salts in each case) dissolved in 10 per cent. ammonia water and made up to 500 c.c., keeps well and the result is very accurate for all purposes; 25 c.c. of the fluid are boiled in a porcelain dish and while hot receives the urine run in 1 c.c. at a time from a burette. This is kept up, the

hot solution being stirred constantly until it becomes colorless. By dividing the constant 2.5 by the number of cubic centimeters of urine used, the resulting figure represents the per cent. of glucose present in the specimen. If this process is repeated and the average of the two processes taken the resulting per cent. will be very accurate.

After the completion of the qualitative and quantitative examination, every diabetic urine should be carefully examined for both acetone and diacetic acid. The testing for beta-oxybutyric acid, the mother substance, is more complicated and need not be carried out; this latter substance which, when existing in sufficient amount, is the direct precourser of diabetic coma, is present in a corresponding ratio to the amount of the former two present. The reactions for both acetone and diacetic acid are easily completed and can be found in any good text book on chemical diagnosis (see Wood's "Chemical and Microscopical Diagnosis"). Arnold's test for diacetic acid is very reliable.

All of the other tests done in routine examinations are to be made, including the specific gravity (most important in diabetic cases), albumin, indican, etc. By making careful records of each examination in the form of charts, and, when necessary, showing these to the patient to inspire his confidence that the case is receiving careful consideration in every detail, even the physician himself will realize that he is doing a great deal more than waiting for the arrival of the diabetic with his accompanying laboratory chart. But unless the physician is able to carry out all of the tests accurately, it would be far better to have fewer examinations made at a laboratory.

In regard to the number of times or rather the interval between urinalyses, the following is sufficient for nearly every case without exception; once a day for three succeeding days when the case is first seen, the patient being on a regular diet, to determine the carbohydrate percentage; almost daily when the carbohydrate toleration is being determined; once a week after the patient has been put on a diet suitable for him; this period after a lapse of about a month can be slowly lengthened until four weeks elapse between examinations after a six months' period, the treatment and course of the disease being satisfactory. All specimens should be twenty-four-hour ones; an occasional specimen freshly voided is advisable when an accurate acetone and diacetic acid reaction is desired for any reason.

Another very simple fact which has been the cause of glucose appearing in the specimen when it should not have, was, in the author's experience, the using of a bottle employed at one time for holding glucose solution. So also bottles not thoroughly cleansed of any syrupy solution must be guarded against. This rarely happens, but if such should happen the physician would be obliged to demand extra specimens from the diabetic, especially if the latter was of a neurotic disposition, a condition not at all infrequently seen among diabetics.

A Few Suggestions as to Treatment of a Diabetic Patient.—Diabetics in general might be classified under three headings: (1) the mild type, in which it is comparatively easy to rid the urine of glucose by means of a suitable diet and a limitation of the intake of carbohydrate food; (2) the intermediate, in which the urine can with more difficulty be rendered sugar-free, viz., by also limiting the intake of protein food; in this type of case the urine at times, no matter what the character of the diet, will contain a slight trace of glucose; (3) the severe form, in which both restrictions or withdrawals of proteins and carbohydrates will not render the urine sugar-free.

In beginning treatment place the patient on a regular diet containing a normal amount of carbyhodrate food for three days, and from three daily specimens of a twenty-four-hour urine get the average percentage of glucose content. If the case is not one of the severe form, or in cases where there is no evidence of any serious complication or danger, where a further reduction in weight will prove disastrous, or in cases where there is no existing severe glycosuria and polyuria or marked acidosis, the following test diet is used. It differs but slightly from the usual test diets employed by others.

	Calories
Breakfast:	
Cup of coffee or tea with 2 oz. cream	100
½ lb. ham with one egg	1125
1 oz. butter	220
Luncheon:	
Two eggs in any form prepared without flour and with butter	200
¼ lb. of meat, vegetables	400
½ oz. full cream cheese	50
Small cup coffee, glass table water	
Dinner:	
Soup prepared with an egg	90
½ lb. meat containing large amount fat or ¼ lb. meat and ½ lb. fish with plenty of butter sauce	950
⅛ lb. vegetables, cup coffee with 2 oz. cream	110
Total	3245

On the first day, in addition to this diet, two slices of ordinary wheat bread are given; on the second day one slice, and on the third no bread at all. As can be seen, this diet contains a very much larger number of calories than a person weighing 150 lbs. would require in the course of twenty-four hours under ordinary exercise. The vegetables allowed are cucumbers, tomatoes, canned asparagus, green asparagus, spinach, lettuce, canned string or little green beans, canned haricot and wax beans, canned okra and Brussels sprouts. All of these contain an average of less than 4 per cent. carbohydrate and some can be employed in the preparation of salad. Since the vegetables are taken in such small quantity, the diet for all purposes might be regarded as being carbohydrate free.

If the case be not one in which the diet is contraindicated, the patient should be kept on this as long as possible up to a period of two weeks; if he is doing well on the diet, even longer. During this time a careful watch must be made of the urine. Acetone and diacetic acid will invariably be found; in cases even where it had not been present before the test diet had been given. During the interval that the test diet is being given the weight will diminish from three to ten pounds in a patient weighing 150 pounds. The patient as a rule will become sugar-free and the polyuria will diminish.

At the time the test diet is begun it is well to begin the administration of bicarbonate of soda in doses sufficiently large to render the urine alkaline and also as a preventive to acidosis. A half ounce a day in divided doses is sufficient. Four parts of this combined with Rochelle salts, one part, serves a double purpose.

The longer this test diet can be kept at without the patient suffering too great loss of weight the greater will be his carbohydrate toleration and the

better the prognosis of the case. To calculate the toleration for carbohydrates wheat bread in one ounce slices are added slowly to the test diet in increasing amounts until the urine begins to show traces of glucose. Since wheat bread averages about 57 per cent. carbohydrate, a diet, which will be more or less permanent, can easily be arranged by substituting other carbohydrate food in place of some of the bread, if desired, the total carbohydrate content not to be any greater than the total amount represented by the patient's toleration for wheat bread; rather is it better to allow it to contain an amount just below the toleration point. In mild cases a diabetic is usually able to tolerate 100 grams of carbohydrate daily, and if a portion of this is represented by wheat bread a very liberal diet made up of different foods containing the lesser amounts of carbohydrate can be taken.

Nearly every mild case of diabetes can be controlled by diet alone, the patient becoming stronger and feeling better; the pains which are present in the calves of the legs in a majority of cases disappear entirely after the urine has been kept sugar-free, the polyuria gradually ceasing, the weight no longer diminishing.

In cases where there is a deficiency in the amount of urine excreted, citrate of potassium is of service; this also may be combined with the sodium bicarbonate along with the Rochelle salts if the latter is required.

A very important symptom needing attention in diabetics is constipation; in some of the cases this alone is responsible for an accompanying acidosis. The use of Rochelle salts or a mild aperient water in sufficient dose to produce a laxative effect is all that is required to correct this tendency.

The skin of a diabetic needs careful attention; the use of a bland neutral soap and an occasional douche in addition to frequent bathing will tend to ward off any serious trouble.

Exercising of the musculature of the body should be insisted upon as by it glycogen is consumed, the patient is benefited, and waste products are eliminated. Almost any form of exercise may be indulged in unless there is a contraindication present in one of the vital organs.

The great tendency for diabetics to possess a somewhat neurotic temperament makes it incumbent upon the physician to divert from the patient's mind anything that may exert a harmful influence. Too frequent examinations of the urine should not be encouraged if the case is progressing satisfactorily, and no one but the physician himself, if he is able, should examine the urine; if examinations are made at a reputable laboratory, reports should be sent to the physician. It has been shown that even though diabetes cannot be caused by a neurotic temperament, the glycosuria is influenced by the latter to a marked extent.

As regards medicinal treatment, the author has not had any experience beyond the use of arsenic in the mild cases where diet alone was not enough to prevent the glycosuria; it is usually unnecessary to go beyond the sphere of diet. In cases where it is necessary, Fowler's solution to the point of toleration is a valuable adjunct.

The discussion of the types of the disease other than the mild type, is not the intention of the author, because of the lack of space in this short paper to cover treatment of the same.

618 West One Hundred and Seventy-ninth Street.

THE LATEST INVESTIGATIONS REGARDING SYPHILIS AND SALVARSAN.

By SAUL STEINER, M.D.,

NEW YORK.

The conclusive discovery of the *Spirochæta pallida* by Schaudinn as the causative agent of syphilis gave fresh impetus to research workers. The subsequent experiments of Ducrey and Levaditi in France, of MacDonough and Wallis in England, Neisser and Unna in Germany, and Noguchi and others in America shed a great deal of light upon the pathogeny of lues. While there is still much work to be done towards clearing up many mysteries regarding this subject, we are at present able to understand much over which the clouds of doubt have heretofore hung.

We will try to answer the following questions:

Firstly.—What happens to the spirochætæ during the 20 or 40 days that they apparently lie dormant in the body of the host that they invaded, until the appearance of the chancre?

Secondly.—What happens to the organism after that? Why that quiescent period of four to six weeks until the appearance of the secondaries?

Finally.—What happens to the spirochætæ when they meet the salvarsan?

The spirocheta is an ultimate development of a sporozoon, a small body consisting chiefly of nuclein, enveloped by a colloidal membrane of lipoid. It is found in all tissues, organs, and humors: pus, serous effusions, urine, blood, saliva, milk, bile, spinal fluid, and has a remarkable predilection for connective tissue.

1. Let us follow the sporozoon from the moment it enters the connective tissue of the skin. Just as soon as it gains entry into a cell the process of development and multiplication starts. The protoplasm of the cell is rapidly reached, the nucleus increases in size, it divides and subdivides so that a rosette-like appearance is formed. This mass breaks up into rods that group themselves in twos, giving the appearance of diplococci. These rods develop into unevenly coiled spirochetes, quite thick, and ultimately become typical *Spirochætæ, pallidæ*. These immature spirochetes resemble the refringens type, so that we can safely say that both the refringens and the pallida are merely stages of the same organism. Naturally, the connective tissue cells invaded by these organisms will offer some resistance, the result of which will be an enormous multiplication. Subsequently they turn into fibrous tissue, so that the part affected will become indurated. This explains the characteristic appearance of the syphilitic primary lesion. Remembering that this process is going on in connective tissue, where there is an absence of leucocytes, we can see very well why there will be a lack of phagocytosis, and consequently a lack of inflammatory process and suppuration. Thus the chancre develops and its insidious attack is all unsuspected. An ulceration of the primary lesion happens only when different saprophytic organisms, which very often reside in those places, interfere.

The time that the spirochete takes to get acclimatized with the new surroundings, to cause multiplication of the connective tissue cells, their transformation into fibrous tissue, and the ultimate ulceration is from two to five weeks and that is the period of incubation.

2. Text books teach us nothing as to what occurs

in the host after the appearance of the initial lesion. All we know is that after about forty days of apparent quietude the skin of the patient is suddenly covered by secondary manifestations and his mucous membranes show special ulcerations. In other words, we find the spirochetes, which have developed in the chancre, making their appearance in localities remote from the portal of entry into the body. How they got there and the route they took make interesting subject for study.

There are two opinions held by different authors. One group considers syphilis a systemic disease, starting at the point of inoculation and becoming generalized very rapidly throughout the organism. Their claim then is that syphilis is a constitutional disease from the beginning and that when the chancre has made its appearance, the virus of the disease has already been disseminated throughout the body. The other group maintains that the luetic infection remains localized to the chancre for a certain length of time and then it gradually spreads to other parts. Members of the first group hold that the virus is rapidly disseminated by the blood —hematogenous infection—that the pathogenic organisms multiply in the chancre and penetrate into the capillary veins and thence to the rest of the body. The opponents to this theory claim that the spirochetes travel along the route of the lymphatic circulation and are thus disseminated.

Let us analyze the arguments of the exponents of these two theories. Ducrey and Queyrat have observed the presence of treponemata in the lumen of the capillaries on a section of a chancre. Neisser has examined chancres and has found the walls of the blood-vessels studded with numerous treponemata. Impressed by this fact, he inoculated monkeys with blood obtained from animals killed during the incubation period, and succeeded in getting positive results. Now let us look closely into these two foregoing facts for the following reasons: If the spirochetes were found in the lumen of the capillary vessels, it does not necessarily prove that it was from there that they made their way into the blood stream. Levaditi has also found treponemata in the capillary vessels, but the lumina of these vessels were obliterated, due to a necrosis of the internal wall caused by a thickening of the adventitia layer of the vessels. Furthermore, the lymphatic spaces around the capillaries were choked with spirochetes. Taking into consideration the histological differences between the capillaries and the lymphatics, we see that the former are endowed with two walls: one endothelial and one adventitia layer; the latter possess only a simple layer of endothelial tissue. It is therefore more reasonable to suppose that the treponemata, like all things traveling a line of least resistance, find it much easier to invade the lymph spaces and canals than the capillary vessels where the resistance is greater and whose walls are pathologically closed.

We cannot very well refute Neisser's experimental findings, because they seem conclusive. Yet, we must not forget that his results have been obtained in the monkey only. It seems that they are exceptional in view of the fact that similar experiments made with the blood of a syphilitic human subject in the full secondary stage (when spirochetes should be most numerous) gave only exceptionally positive results.

There are more arguments against the theory of the propagation of the spirochetes through the blood-vessels, chief among which is the following very logical one: If the spirochetes were to find their way into the blood stream via the vessel walls, that is, if they were present in the blood before the appearance of the chancre, how does it come about that the patient thus afflicted is not yet in an infectious stage? It is a well-known fact that many physicians, especially surgeons, have been in contact with the blood of syphilitics in the prechancrous stage and were not infected. Also persons in and out of wedlock have had intercourse during that period without contagion. It must therefore be admitted that the blood is not contagious during the incubation period and that the generalization of the virus goes on very slowly.

In corroboration of this we find that the Wassermann reaction remains negative during the incubation period, and it is only from fifteen to twenty days after the appearance of the initial lesion that the reaction becomes positive. A positive Wassermann means a generalization of the virus in the blood, the presence of antibodies, while a negative reaction excludes the presence of antibodies and therefore there is no generalization.

Summarizing the arguments which make one lean to the theory that the microorganisms choose the lymphatic system as their line of invasion, we find the following array of facts:

1. The meager defences of the lymphatics—a thinly guarded wall of endothelium—make it a simpler matter for the invaders to enter than if they took the harder path to traverse, the strongly guarded walls of the capillaries.

2. The immediate onset of a lymphangitis following the invasion of the spirochetes and subsequent enlargement of the group of glands nearest to the site of infection.

3. The lymphatic channels and glands upon examination immediately after the appearance of the chancre have been found full of spirochetes, whereas the blood capillaries only occasionally show a few undeveloped forms of the microorganism clogged up in a localized endarteritis.

4. The blood of the patient is not able to carry contagion in the prechancrous stage.

5. Another proof in favor of this opinion is deduced from the action of salvarsan. The fact has been demonstrated that the introduction of salvarsan may provoke the Herxheimer reaction; the explanation of this phenomenon lies in the destruction of the spirochetes and the liberation of syphilitic antibodies which they contained. The frequency of this phenomenon depends upon the number of spirochetes found in the blood. That is to say, the greater the number found the more frequent is the reaction. It is also an accepted fact that this reaction is very frequent when salvarsan has been administered during the secondary period of the disease, and is not observed at all when given the first ten or fifteen days after the appearance of the chancre, showing that the generalization of the spirochetes is an accomplished fact only at the end of the second period of incubation.

Now then, for the purpose of illustration, let us begin at the site of infection, say of the penis, and see what occurs thereafter. The spirochete invades a connective tissue cell, develops and multiplies there without causing any alarming or even suspicious symptoms. Little by little the organisms make their way into the lymphatic channels and without a great deal of opposition reach the inguinal glands. Here for the first time they encounter some degree of resistance. The leucocytes form the

first line of intrenchments, ready to oppose the further advance of the invaders. And here also, as on the battlefield, victory will lie with the side possessing the greatest numerical strength. The continuous stream of new armies of spirochetes coming from their base, the chancre, enables them to gain the victory, and leave in their wake the dead bodies of leucocytes. An inguinal adenopathy is the result. A further advance on the part of the invaders and they are again opposed by a new relay of glands. Another battle, and another resultant adenopathy. Thus they progress from ganglionic relay to ganglionic relay, they arrive at the thoracic duct, then in the subclavian vein, from where they finally enter the blood circulation. Immediately after that we witness the appearance of the secondary manifestations. This is what happens during those 30 or 40 days that pass from the appearance of the initial sore until the appearance of the roseola. It is then a long and hard fight put up by the spirochetes to overcome the opposition of the glands, and their multiplication. From then on there is a continuous fight between the invaders and the antibodies, which are now elaborated by the organism. Unhappily the spirochetes like the connective tissue, where the leucocytes are at their minimum and the antibodies do not penetrate. There they go and intrench themselves strongly. The organ or tissue becomes less resistant and the spirochetes gain the ascendency—a gumma makes its appearance.

This fight for supremacy goes on for years and years with occasional sorties of the invaders from their intrenchments in the connective tissue, the bones, the arachnoida, meningeal membranes, etc., where they are comparatively safe from destruction and where they are continually proliferating and bringing up new and fresh reinforcements to the attack.

Now we shall see to what practical uses we can place the knowledge that we have thus acquired and how best to judge the effect of our newest and most powerful howitzer in our therapeutic armamentarium—salvarsan.

In order to answer this question intelligently, we must review again the biography of the spirochete. The syphilitic parasite consists chiefly of nuclein that is enveloped in a membrane of lecithin-globuline. This membrane is richly impregnated with an unsaturated fatty acid; but that condition is found only when the parasite occurs in a mature form; in the immature form of the spirochetes this fatty acid occurs in a saturated form.

It is a known fact that the more unsaturated a fatty acid is the more free hydroxyl (OH) groups will there be to unite with different chemical substances that possess an affinity for them. The *Spirochæta pallida* therefore, by virtue of the many free OH groups that it contains, attaches to its lipoid envelope or membrane many substances with which it readily combines, and is altered greatly as a consequence.

In this way salvarsan, with its large content of arsenic, upon coming in contact with the *Spirochæta pallida*, unites with the free OH groups of its lipoid membrane, robs the spirochete of its oxygen and thus destroys this pathogenic organism. But, here the question of the immature forms of the spirochete comes up; and it is this group that prevents us from getting in salvarsan the long-looked for remedy for all syphilitic manifestations. These immature forms contain a saturated fatty acid, and consequently no free OH groups; and the introduction of salvarsan into the circulation will in no way be inimical to their life and development. This forms the basis for explanation of cases in which salvarsan in repeated doses has had no curative effects. Some hidden focus, which keeps on producing new spirochetes, evidently exists in these cases. As the organisms mature, they are readily destroyed by the salvarsan that is repeatedly introduced; but the immature forms, uninfluenced by the drug, serve to keep the disease dormant, ready at any time to spring up again.

It is also reasonable to believe that some spirochetes are locked up in thrombosed vessels and within sclerosed areas where they are inaccessible to salvarsan in the blood circulation. Subsequently, when the processes of repair have opened out these sclerosed areas, long after the dose of salvarsan has been excreted, the surviving spirochetes escape into the tissues and reinfect the patient. That must be the reason that syphilis is so hard to cure, and also the reason why salvarsan has been so much maligned. So hot has the controversy waxed that many authorities have felt called upon to say that salvarsan does not cure syphilis, but is only a great and powerful symptomatic curative agent. The foregoing proofs, however, and the fact that the organisms disappear from the chancre immediately after the administration of the salvarsan, consequently, that salvarsan does actually kill the *Spirochæta pallida*, are sufficient proofs of the fact that it is not merely an agent for the symptomatic treatment of syphilis, but a bona fide cure for the disease.

This is only a theory based upon chemical facts. There is another view of the question which should be taken in consideration. In cases of meningeal or spinal syphilis, or parasyphilitic lesions, where the parasite is demonstrated to exist, the usual injections with salvarsan have not been successful. But the salvarsanized serum has given much better results than when the salvarsan infusion was introduced even directly into the spinal column. In other words the parasite was not destroyed by the direct action of salvarsan. How did it act in these cases? It has therefore been assumed that the remedy, when introduced into the blood circulation, produces some kind of substances, the character of which is, at present, not known, and which have the property of killing the *Spirochæta pallida.*

Whether the salvarsan has a direct or an indirect action on the spirochete the fact remains that it kills the parasite. If the spirochete disappears from the chancre after the administration of salvarsan it is reasonable to admit that it must disappear also in the organism. It is only left to us to discover ways and means of administering the drug in a way best suited to effect a permanent cure.

The first thing, therefore, to do is to effect the extermination of the supply base, the chancre. Excision of the primary sore, when suitably situated, should be performed as soon as the patient is seen (and the diagnosis is made, by the proper identification of the spirochete), even under the penalty of giving the patient an ugly scar. We do not mean to say that in this way the disease is aborted, or eradicated, but we rid the patient immediately of a spot that sends thousands and thousands or organisms into the circulation in an unending stream. So it is easy to see that the fewer the number we have to deal with the more efficacious will be our remedy.

The second step should be the administration of

salvarsan. This drug, powerful as it is, has the inconvenience that its elimination from the body is too rapid. Its action therefore necessarily extends over too short a period. This shortcoming can be met very easily by the frequent introduction of the drug into the circulation. Infusions of salvarsan given at long intervals will be of no avail in the combat against the disease, while the salvarsan introduced will serve to kill the pathogenic organisms that exist in the circulation; the armies of those forming behind them will not be affected. So that, since it takes about five to eight days for the elimination of the salvarsan after it has been introduced, it would be safe, as well as logical, to administer the next dose after five or eight days have elapsed.

Finally, we can deduct also that maximum doses should be used, because small doses, even repeated, have not enough power to kill a large number of organisms, and also because they make the organism arsenic fast, helping thus to defeat the purpose for which the drug was intended.

17 Livingston Place.

THE BELGIAN RED CROSS HOSPITALS OF DR. DEPAGE.*

By C. L. Gibson, M.D.,

New York,

Surgeon to the New York Hospital.

Dr. Antoine Depage of Brussels has an international reputation as a surgeon, and is particularly well known to his surgical colleagues in America. The International Surgical Society had its birth in Belgium, and all its meetings, with the exception of the last, were held in its beautiful and hospitable capital. Depage was the original Secretary General of the Association, and the success of this society was largely due to his extraordinary capacity as a worker and organizer. These qualities obtained recognition in his election as president of the association when he had finally served the three consecutive terms as secretary to which the tenure of office is limited. The hospitality and courtesies extended to foreign surgeons and their families by the Belgians, and particularly by Dr. and Mrs. Depage were, I think, particularly appreciated by us Americans. Though our delegation was ordinarily quite small in number, we all felt that no country could have been treated with greater consideration or distinction than was accorded to our representatives. It is but natural, therefore, that in this sad conflict the work of Prof. Depage as head of the Belgian Red Cross should be of peculiar interest to the Americans.

Depage has been for many years the leading surgeon in Brussels, and surgeon to his Majesty, King Albert. Although he was carrying a load of tremendous responsibilities, he did not hesitate two years ago when the Balkan war broke out to abandon everything to take charge of the Turkish Red Cross. His achievements on that occasion have obtained universal and deserved recognition. It furnished him necessarily with an experience which he was destined to give in the relief of his own stricken country.

With Dr. Melis, surgeon general of the Belgian Army, he has been put in charge of the Red Cross in Belgium, working also as a member of the Belgian Army with the title of lieutenant-colonel. His specific duties in the Belgian Red Cross are particularly with the military, and the wounded rather than the sick.

Knowing Dr. Depage very well, I was very glad recently to accept his invitation when visiting Europe to join him in his present field of activities. He has organized and is working two hospitals. One, which might be described as a base hospital, is at Calais. When I was there the institution had been open for work for four months, and the results accomplished in that time are an eloquent testimonial of the efficiency and determination of the man. The building is a fairly modern large girls' boarding school, its spacious class rooms and dormitories being easily transformed into practical and pleasant wards. There was no suspicion at first sight that this was a recent and temporary institution. It looked fully as well equipped as do many permanent institutions. All the ordinary equipment of a well regulated surgical hospital and operating plant, up-to-date *x*-ray apparatus, pathological laboratory, disinfecting and sterilizing plant, were all that could be desired. The most eloquent testimonial of the efficiency of the hospital was the admirable condition of the patients and the number of surprisingly smooth convalescences from severe conditions often requiring extensive operations. The hospital was then in charge of Dr. Nieman, one of Depage's younger surgical colleagues from Brussels, and the work so magnificently begun was being carried out equally well.

When this Calais hospital had been organized and running three months, Depage started a field hospital at La Panne in Belgium, and his new plant had been in operation a month when I visited him. To get to La Panne from the south one has to pass through Furnes, a beautiful medieval town, the last of its kind left in Belgium. The Germans began bombarding it last fall, and although the town has long been absolutely evacuated, it continues to be bombarded intermittently though this operation is devoid of military value. Some shells fell in the town the day I passed through it. La Panne is on the sea coast, 80 kilometers north of Calais. It is situated in the tiny strip of Belgium that is at present not occupied by Germans. It is therefore only a few miles north of Dunkirk, situated at the Franco-Belgium border. It is about 30 miles south of Ostend—normally a quiet seashore resort made up mostly of villas. It did not furnish, except for its attractive and healthy situation, much material for the installation of a hospital plant. There is only one considerable sized building in this village, a typical summer hotel. This building had been fitted up as a hospital to accommodate a hundred patients. The convalescent overflow is evacuated from time to time on to the hospital at Calais. Although Depage had been installed in this field hospital only a month he had an absolutely satisfactory equipment. His twin operating rooms were well fitted up and the lighting and sterilization plant complied with modern standards. In fact, I have in mind hospitals in New York City that do not possess so attractive and convenient an operating equipment. Adjoining the operating room was a good *x*-ray apparatus in the hands of a very competent operator. The building, not lending itself to the formation of small wards, the patients were grouped two to four in the hotel bedrooms. The main drawing room of the hotel, with a beautiful view of the sea, had very wisely not been converted into a ward but was used admirably

*Read before the New York Practitioners' Society, April 2, 1915.

as a comfortable lounging room for the convalescents and the personnel of the hospital.

The nursing was admirably done by a competent and sufficient corps of English nurses. Acting as assistants to Depage were a number of younger medical men, mostly Belgians, and an occasional foreigner—French, English, and one Canadian. These younger assistants each had charge of a certain number of patients, taking full care of them, performing such operations as were delegated by Depage to them. All these workers, medical, lay, or military, were regularly enrolled in the Belgian Red Cross. This procedure is necessary in order to have control of the personnel and make it responsible to the single authority, which is Depage.

The hospital at La Panne is in close proximity to the line of the opposing armies situated along the River Yser. It is only two miles from the rear trenches and from the hospital sounds of cannonading can be heard constantly, and at night the explosion of shells is often seen, particularly when the Germans throw up the luminous bombs, which give an extraordinary illumination of a large area of territory. This close proximity to the firing line allows of giving prompt and efficient treatment to the wounded. Hence, the many disastrous results consequent of long neglect of these unfortunates in other portions of the line are wanting.

The hospital is well equipped with a corps of motor ambulances, which are running back and forth to the trenches constantly, and particularly at night, when they are less likely to form a target for the opposing forces. I saw a soldier who had been wounded by a fragment of shell in the trenches at 3 o'clock. He received on the field very efficient first aid treatment—wound disinfection with iodine, and a large and secure dressing applied. He was brought to the hospital in an ambulance, examined by Depage at once, was taken to the *x*-ray room, the plate developed, and was then anesthetized, a fragment of shell removed, and he was returned to bed in the ward at 6 o'clock.

In addition to the actual work performed in the hospital, Depage also has the problems of looking after the hygiene of some 10,000 soldiers quartered at La Panne. These soldiers are either raw recruits undergoing training, or are groups of men taken out of the trenches for a few days' rest. Bath houses, laundries, and sterilizing plants are being erected for their comfort.

So much for the past! At present, Depage is looking actively ahead to the problems which future fighting will bring about. It is his hope and intention to make La Panne, on account of its good situation and healthy climate, a base hospital of about a thousand beds, and at the present moment barracks are being actually erected for three hundred beds. Barracks have to be erected, as there are no suitable buildings in existence. It is Depage's purpose to have in readiness a field organization and equipment that he can carry with him to the firing line if that line moves to the East and North as the Belgians and Allies expect. On this theory, Depage expects to equip new field hospitals at Ostend, Ghent, and so on, according to the necessities of the situation.

With a man of Depage's capacity and ability to plan and look ahead, and the courage and force to carry through big movements, a large proportion of the work is already accomplished. Much equipment will have to be provided, and money is an absolute necessity. We in America have, of course, done much for the Belgians, and much more still remains to be done. As the largest and richest neutral nation we are free from our own responsibilities to give relief which the combatant nations like France and England can hardly do, as they have their own gigantic problems to handle.

As regards the possibility of American doctors working in connection with Depage and the Belgian Red Cross I am authorized by Dr. Depage to state the following:

That he would welcome heartily any American surgeon. He would like them to come in one of two ways, either as volunteer assistants, especially younger men, who should act directly under him in charge of a certain number of patients in his hospitals, or he would like very much to have American units organized and headed by surgeons of well established repute, these units to be preferably fitted to take care of fifty or a hundred patients. To such units Dr. Depage would give complete control, putting them, as he says, directly on a parity with him. The Belgian Red Cross could supply such units with food, both for patients and personnel, and dressings. Everything else, however, would have to be supplied by such a unit, including the construction of hospitals and barracks, as in devastated Belgium there will be practically no buildings available. Temporary barracks, though, can be built quickly and quite cheaply. American tents and knock down portable buildings can also be utilized to great advantage in many ways. He can also utilize a large number of automobiles and drivers. In addition to the ambulance automobiles, he requires a considerable number of large, powerful trucks for the transportation of material.

I may add from my own observation that any unit intending to join Dr. Depage should have at least one person in authority with a pretty fluent knowledge of the French language. Moreover, I would suggest that to each unit there should be a lay worker, a person preferably used to questions of organization, the obtaining of supplies and material, and used to handling personnel. It seemed to me that in quite a number of instances our American surgeons were swamped in the details of organization that might be termed "housekeeping." That work could be better turned over to some properly qualified person and the surgeon give up more time to the purely surgical problems.

Dr. Depage feared that with the progress of the war his very competent English nurses would no longer be available. He is desirous of obtaining American nurses, whose capacities he thoroughly appreciates. Unfortunately, the Belgian Red Cross is in no position to pay American salaries. On the other hand, it is absolutely wrong to expect hard working and ill paid American nurses to devote their earning power as so many have generously done. Here is a field for private benefactors. It may be stated that there is no room at the front for the amateur nurse.

72 East Fifty-fourth Street.

Pneumothoracic Pleurisy.—A. Faginoli has made a study of this condition, which as its name indicates, is the pleurisy following the operation of artificial pneumothorax. He has observed it twenty times among thirty-five patients subjected to this method of treatment. In only one instance did it seem to shorten life, in all the other cases it interrupted, retarded, or limited the advantage of the treatment, but did not seriously affect the latter.—*Riforma Medica.*

New York, April 24, 1915.

THE CHEMOTHERAPY OF TUBERCULOSIS

DURING the past few years there have been carried out in the Sprague Memorial Institute and in the Pathological Laboratory of the University of Chicago a number of investigations on the chemotherapy of tuberculosis. The results have been published largely in recent numbers of the *Journal of Infectious Diseases*. A survey of these studies has been made by Robert Lewin, and is contributed to the *Zeitschrift für Tuberkulose*, February, 1915. The subject is one of engrossing interest, particularly in view of the prominence that is now being given to the rôle of chemotherapy.

Wells and Hedenburg have shown that the point of attack in the chemotherapy of tuberculosis, in contradistinction to that of all other forms of chemotherapy hitherto attempted, is a region poor in blood vessels, namely, the tubercle. This explains the negative results obtained in all the empirical attempts at chemotherapy in this disease, the failures being attributed to the inability of the chemical agents to gain access to the nonvascular areas. Another factor that accounts for the futility of a therapia sterilisans magna in tuberculosis is the circumstance that the tubercle bacillus unlike other microorganisms has a peculiar fatty and waxen envelope. Of prime importance, therefore, was the investigation of the permeability and lipoid-solubility of the tubercle bacillus. It was found that the administration of iodides to tuberculous animals led to a deposition of considerable amounts in the tubercles and caseous foci, but not to any greater extent than in necrotic non-tuberculous foci in other animals. In other words, the affinity of tubercles for the iodides is not a specific one, and is the expression of a physico-chemical phenomenon rather than of a chemical reaction.

Considerable light has been thrown upon the subject by the investigation of the vital staining of the tubercle bacillus. Corper fed tuberculous guinea-pigs with fat-soluble dyes, but could not detect even traces of these substances in the bodies of the tubercle bacilli. Such dyes as sudan III, scarlet red, etc., would stain the depot fat in the body, but would not stain the cells of the parenchyma. Lydia M. de Witt made a thorough investigation of the subject of the vital staining of the tubercle bacillus. She found that in guinea-pigs trypan blue, trypan red, isamin blue, methylene blue, etc., penetrate the tubercle. They are well borne by the animal, provided the dose is not too large. The tubercle bacillus is likewise stained by methylene blue, basic fuchsin, crystal violet, erythrosin, and eosin. With skepticism, however, is regarded von Linden's report of a curative action of methylene blue in tuberculosis. Although this drug has a bactericidal action upon the tubercle bacillus no definite therapeutic results have been obtained with its administration in tuberculous animals.

The efficacy of copper compounds in the therapy of tuberculosis has not been proved. Corper, de Witt, and Wells could not detect any special bactericidal property in the copper compounds, including the lecithin preparation for which strong claims have been made. Nor has Corper been able to detect any special affinity of the copper compounds for the tubercles. In fact, colloidal copper does not penetrate the tubercle. The crystalline compounds of copper are converted into the colloidal form immediately after administration. Wells and Hedenburg have shown that colloids are unable to gain access either to the tubercles or to necrotic foci.

Although the results thus far obtained in the chemotherapy of tuberculosis are far from encouraging, it is to be hoped that investigations along this line will be continued with increased energy and will yield results of definite practical value.

POSTURE AND DIGESTION IN INFANCY.

THE "modern method" of bringing up the baby is in many ways radically different from the "old-fashioned" method and in none more so than the question of feeding. Old sayings and grandmother's advice are here all firmly entrenched and the conflict between the young mother and the grandmother at times becomes acute. The physician trained in the scientific school is only too apt to laugh at the old-fashioned empiric advice and yet it is probable that each old saw has at heart the necessary grain of truth that keeps it alive. For many years the modern teaching was that an infant, after feeding, should not be joggled about, but should be laid in its crib and allowed to go to sleep. Only too often the child refused to sleep, but lay and howled lustily to the disturbance of the neighbors and the distress of the mother. The mother is greatly chagrined if the grandmother picks the child up, holds it on her shoulder a minute and pats it gently and then sees it go to sleep almost as soon as it is laid upon the bed.

The old lady would say that the trouble was due to gas in the stomach and Smith and LeWald have recently shown (*American Journal of the Diseases of Children*, 1915 IX, 261) by the use of radiographs that she was right. They explain how an infant taking liquid food is unable to avoid swallowing a certain amount of air with each act of deglutition and then present radiographs that show stomachs often enormously dilated, largely with gas, immediately after feeding. This gas on analysis proves to be air, for only in cases of extreme gastric stagnation is the gas formed in the stomach. As soon as the child is held erect and patted gently

on the back it eructates the gas and becomes quiet and the radiograph shows that the stomach is now contracted down upon and is completely filled by the food. This process is due in a measure to the relation of the parts so that if the stomach is partially filled with fluid and the child in the horizontal position, the gastric contents rise above the esophageal opening, forming a good water-trap and preventing the escape of the gas into the esophagus. The authors above mentioned are firmly convinced that many cases of vomiting are due to this gastric distention and that it is better for the child to take its feeding rapidly, for then the number of swallowing acts are fewer and the amount of air in the stomach is less. Vomiting hitherto thought to be due to too rapid feeding they think is due rather to overfeeding. In hospital patients who are permitted to lie in bed for long periods a chronic dilatation may result. The importance of thus holding the child erect after the feeding is one that is apparently neglected by most of the textbooks, and in view of the erroneous teaching of the past it is worth while to lay some special emphasis on the subject at this time.

TISSUE TRANSPLANTS AS HEMOSTATICS

In July, 1914, Horsley called attention to the value of a small bit of muscle or other tissue as an efficient hemostatic when placed in contact with a bleeding point. He was not the first, however, to suggest the use of tissue transplants in the treatment of the bleeding following injury to various organs. Levy, Boljarski, and Girgolaw proposed the use of free transplants of the omentum in the treatment of hemorrhage from the liver, and this method has been employed with success by others in the treatment of wounds not only of the liver but also of the spleen and kidney. Fat has also been used in the same manner in the treatment of similar injuries. During the past year a number of investigations have been conducted along this line. Waljaschko and Lebedew have shown the feasibility of staying the hemorrhage from wounds of the liver by means of transplants of superficial fascia from the abdominal wall. Läwen and Jurasz have reported the results of their experiments in controlling the hemorrhage from wounds of the heart and other organs with the aid of bits of muscle superimposed upon the wound.

Augusto Pignatti (*Il Policlinico*, January, 1915) has performed a series of investigations on the rabbit and guinea pig in order to test the comparative value of different tissues as hemostatics. He found that there is no difference in hemostatic power between transplants of omentum, fat, aponeurosis, and muscle in the treatment of wounds of the liver, kidney, and spleen. In studying the fate of the transplanted tissue it was found that this is subsequently replaced by newly formed connective tissue. Similarly good results in hemostasis were obtained with the use of a nonliving, organic, absorbable substance such as the ordinary sponge, which has the advantage of absorbing blood, and by its increase in size, exerting a light compression on the bleeding point. The sponge is similarly replaced later by new connective tissue.

SOME PHASES OF THE AFTER TREATMENT IN ABDOMINAL OPERATIONS.

The after treatment in the case of a serious operation is as important to the welfare of the patient as the performance of the operation itself. Indeed, however skilfully an operation may have been performed, if the subsequent supervision of the patient is not carefully and competently carried out, the skill of the operator will go for naught. Therefore a great deal of the responsibility for the successful outcome of, for instance, an abdominal operation, will fall upon the local practitioner. Reference is made to those cases which are operated upon in a country district and to treat which the surgeon has to travel a considerable distance.

In the *Medical Press and Circular*, Feb. 17 and 24, 1915, is published a paper on the after treatment of abdominal operations by Mr. Albert Carless, Professor of Surgery in, and Surgeon to King's College Hospital, London. With regard to feeding after abdominal operations, it is pointed out that this has undergone great modifications in recent years as a result of increasing confidence in aseptic technique. Formerly patients were starved for nearly a week; now the surgeon's desire is to restore the normal activities of the intestinal canal at the earliest date, and where there has been no interference with the continuity of the bowel there is not the slightest reason why the patient, if he desires and feels capable of taking it, should not be given his ordinary food the next day. As for the quenching of thirst, this is best relieved by the administration of saline solution by the bowel, either continuously or in doses of a pint at a time at six-hourly intervals. In enteroanastomosis a little more care has to be taken with the administration of food, but even in gastroenterostomy the present-day methods of suture are so perfect that the risk of leakage need hardly be taken into consideration. Carless recommends as purgative measures that a turpentine enema be given on the day after operation when the patient generally suffers from distention and some colicky pains. On the second or third day an ordinary routine purgative is necessary in most instances, and the patient may be given castor oil or calomel. Subsequently the bowels are kept acting daily by senna, cascara, or some other mild laxative.

It is important after an abdominal operation to stop or abate vomiting, which is, of course, a common sequel. Carless in such a juncture mainly pins his faith to turpentine enemas and believes in lengthened rest in the treatment of the external wound and as a means of strengthening the abdominal wall. Exercise must be taken with discretion, as one has to steer the patient between the Scylla of inaction and the Charybdis of overexertion.

CONTROL OF MALARIA.

Oiling of water surfaces in order to prevent the spread of malaria should be a supplementary measure to proper drainage. But when funds are not available for drainage, oiling will largely control the propagation of mosquitos. Dr. J. A. A. Le

Prince, Sanitary Engineer U. S. Public Health Service, writing in Public Health Reports, Feb. 26, 1915, points out that the object to be attained in using petroleum or other oils is to destroy the larvæ of mosquitos. To effect this object the surface of the water must be completely and continuously covered with a film of oil. The results thus produced in preventing mosquito breeding are: (1) Where mosquito larvæ are present such larvæ cannot penetrate the oil film with their breathing tube, and therefore die, and (2) mosquitos do not lay eggs on the oiled surface of the water.

Oil may be applied to water surfaces of pools, ditches, streams, shallow lagoons, and edges of deep ponds, lakes, and rivers, when necessary. Larvæ of mosquitos are not found in bodies of water of considerable depths, unless aquatic plants, algæ, or debris are present, but are seen near the banks of such bodies of water. Oiling is not advisable in such cases when the film will not remain effective, as just before rainstorms.

The writer describes the various methods of oiling water and points out that it is advisable wherever possible to have a map of the district showing the location of all streams, ditches, pools, and other possible mosquito-production areas. The employment of oil cast on water to prevent the spread of malaria has everywhere been attended with highly satisfactory results, but, undoubtedly, as Le Prince shows, it must be carried out carefully, with due attention to details, to bring about the best results.

Formation of Bone Callus.

This subject is in a rather confused state at present. Much work is being done in animal experiment, but the deductions therefrom are somewhat conflicting. In man we have a new teaching based on *x*-ray studies, and it is evident that the entire subject will have to be rewritten with incorporation of much material hitherto disregarded. At a meeting January last of the United Medical Societies of Berlin (*Münchener medizinische Wochenschrift*, February 2) von Hansemann denied the old belief that callus production is superabundant. In the modern day of more accurate coaptation by aid of *x*-rays much less callus is formed than in the old days. As a rule, the greater the lack of coaptation, the greater the production of callus. In addition to coaptation and even more important is muscular pull. When this is present more callus is formed. In other words, whatever favors consolidation tends to do away with the need of callus. Broken bones under certain conditions can unite without callus formation. This can be studied in the skull bones. Large fractures with great displacements may heal so thoroughly without callus formation that the fracture line cannot be discerned. As muscular pull is so important a factor the prognosis for healing must be better in proportion as the break is distant from a muscular insertion.

Synthetic Camphor.

A large volume could doubtless be compiled on the enforced substitution of drugs which has come about in history through warfare, tariff changes, monopolies, and numerous other causes. In the present war the Germans have been compelled to use all their technical skill to meet the deficiency of imported drugs. Synthetic chemistry is adequate so far as it goes, as well appears from a communication by Kaufmann to the military supplement of the *Muenchener medizinische Wochenschrift*, March 2. Medicinal camphor had before the war been obtained from Japan, and had been used exclusively in medicine despite the fact that records of the availability of synthetic camphor had been on file for ten years without having been published. Upon the failure of the imported drug the author at once began tests of the synthetic form and to date had treated forty cases of the most severe external lesions in which camphor acts as a sedative—varicose ulcers, cancer of the face, bullet wounds, furuncles, suppurated buboes, gummous ulcers, hard and soft chancres (some phagedenic). He found that synthetic camphor not only surpasses natural camphor in medical efficiency, but that it is of greater purity, a better disinfectant, and at present cheaper in cost.

News of the Week.

More Red Cross Surgeons Sail.—Five Red Cross surgeons and twenty-four nurses sailed for Europe last Saturday by the American liner *St. Louis*. With the exception of one of the surgeons, the party will go direct to Belgium, to report there to the Belgian Red Cross. The *St. Louis* carried also a great consignment of hospital supplies, including two complete field hospitals.

Belgian Relief Ship Torpedoed.—The Belgian Relief Ship *Harpalyce* was torpedoed and sunk in the North Sea near the coast of Holland on April 10, fifteen of her crew of forty-two being drowned. She had just discharged her supplies at Rotterdam.

Belgian Red Cross Suppressed.—The branch of the Red Cross operating in the part of Belgium under German control has been dissolved by the military governor of the country, its work being taken over by the Germans under Count Hatzfeldt-Trachenberg.

French Army Surgeons Slighted.—The War Department of France has ordered that the rank of the army surgeons be indicated by silver stripes instead of gold so as to avoid confusion between officers of the line and those of the medical corps. The surgeons say the silver stripes indicate that the wearers are non-combatants and they declare they must be considered as real combatants. This is supported by the fact that after the infantry the medical corps shows the highest average of killed and wounded.

To Enlarge the American Hospital at Juilly.—So many wounded are brought from the front to the hospital at Juilly, the auxiliary to the American Ambulance Hospital in Paris, that the accommodation is taxed, and preparations are being made to enlarge the institution from 130 beds, its present capacity, to 400. Dr. George Brewer of this city will, it is reported, go over in May to work in the hospital. A call has just come over for more nurses and more doctors.

American Ambulance Trains for Germany.—Three hospital trains, each of an automobile with two trailers, have been presented to the military commander at Frankfort-on-Main by friends of Germany in the United States. Mrs. Taylor, an American living in Frankfort, was chiefly instrumental in arranging for the gift. One of the trains will be attached to the army of the Crown Prince,

another to that of General von Hindenburg, and the third to the Eighteenth Army Corps.

For a New York Physicians' Ambulance.—The British War Relief Association has issued an appeal for subscriptions of $10 each for the purchase of another motor ambulance for the American Volunteer Motor-ambulance Corps operating on the battle line in France. The ambulance will be known as the New York Physicians' Ambulance. The treasurer of the fund is Mr. James Chittick, 132 West Twenty-seventh street.

The Belgian Red Cross.—In connection with the account by Dr. Gibson of Dr. Depage's Red Cross work in Belgium, published in another column of this issue, the following extract of a letter from this distinguished surgeon, President of the International Congress of Surgery which met in this city a year ago, is of interest. The letter appears in the *Boston Medical and Surgical Journal* of April 15. "The situation in which we find ourselves is truly tragic. The Belgian Red Cross finds itself confronted by conditions which are unique in its history. The country, after an heroic defense, has been almost entirely overrun; its cities destroyed, buildings annihilated; installations confiscated by the enemy; its resources wiped out. That is the sad picture it presents. The Belgian population has been compelled to flee the country; our wounded are forced to seek asylum in foreign lands. Others have told you, others will tell you again, of the pitiless character of this war. As for me, as a doctor, I wish during the war to occupy myself with but one thing,—the care of the wounded. My sole preoccupation is to save human lives, and sometimes to save what is more precious than life, when by preventive measures we can save the wounded from becoming crippled for the rest of their existence. And so I face the situation in which our Red Cross work finds itself in this war, and I seek for means to assure to our soldiers the care which they expect from us. We have before us a ravaged country which offers no shelter for our hospitals, no implements, no resources of any kind. We are, therefore, face to face with the necessity of reconstructing entirely our hospitals and ambulances and of furnishing them completely with all necessary supplies. . . . America, I know, has already given generously to Belgium. Encouraged by your brotherly sympathy, I ask you for still more, and I send you my faithful collaborator, Madame Depage, who accompanied me on my last visit among you. The Managing Committee of the Belgian Red Cross has appointed her for the purpose of organizing, in its name, an American-Belgian Committee which will centralize all contributions and forward them directly and promptly, so that we may continue our work and meet our needs."

Committee of American Physicians for the Aid of the Belgian Profession.—The following is report of the treasurer of contributions received during the week ending April 17, 1915:

Fort Wayne Medical Society, Fort Wayne, Ind.	$25.00
Ramsey County Medical Society, St. Paul, Minn.	25.00
The New Castle Physicians Club, New Castle, Pa.	10.00
The Harrison Co. Medical Society, Gulfport, Miss.	25.00
The Cumberland Co. Medical Society, Portland, Me.	25.00
The Waterbury Medical Association, Waterbury, Conn.	13.00
Dr. William T. Hamilton, Philadelphia, Pa.	5.00
Dr. Charles Alfred Dukes, Oakland Cal.	5.00
Dr. P. St. L. Moncure, Norfolk, Va.	5.00
Dr. R. T. Stratton, Oakland, Cal.	5.00
Dr. R. J. E. Scott New York, N. Y.	5.00
Dr. W. C. Cahall, Germantown, Pa.	2.75
Dr. Richard Dewey, Wauwatosa, Wis.	10.00
Dr. E. H. Ruediger, Manila, P. I.	10.00
Dr. Lucretius H. Ross, Bennington, Vt.	10.00
Mr. A. W. Burnham, Pittsburgh, Pa.	5.00
Receipts for week ending April 17.	$185.75
Previously reported receipts.	6,138.75
Total receipts	$6,324.50
Disbursements for week ending April 17, 80 Standard Boxes of food, at $2.30.	$184.00
Previously reported disbursements: 1,625 Standard Boxes of food, at $2.20.	3,575.00
1,114 Standard Boxes of food, at $2.30.	2,562.20
Total disbursements	6,321.20
Balance	$3.30

Examination for Clinic Physician.—The Municipal Civil Service Commission of New York announce an examination for clinic physician at a salary of $1,200 to $1,500 per annum. The duties are to supervise the various clinics (tuberculous, venereal, and antirabic) of the Department of Health. Hours of service are three hours daily, six days a week. Candidates must be 25 years of age or over, be licensed to practise in this State, and have had one year's experience as interne in hospital or sanatorium, or two years in out-patient work. Applications will be issued at Room 1400, Municipal Building, from April 15 to April 29, at 4 P.M. Four cents postage must accompany requests for application blanks by mail.

Dr. A. Jacobi Division of the German Hospital.—On Sunday of this week two new buildings of the German Hospital were opened with appropriate ceremonies. One building was for the use of private patients, the other was the children's hospital, to be known as the Dr. A. Jacobi Division of the German Hospital. The hospital, largely planned by Dr. Charles Goodman and made possible by a gift of $150,000 from Mrs. Anna Woerishoffer, is perhaps the most complete establishment of its kind in the world, containing all the best features of other children's hospitals and having a number of novel ones. At the opening exercises addresses were made by Mr. F. Achelis, president of the hospital association, Dr. A. Jacobi, Mr. George McAneny, president of the Board of Aldermen, Dr. G. Seeligman, president of the medical board, and Dr. Carl Eggers, president of the Junior League.

Presentation of a Portrait of Dr. Mall.—At the recent commemoration day exercises at the Johns Hopkins University an oil portrait of Dr. Franklin P. Mall, professor of anatomy, was presented to the university. The portrait was painted by Mr. Seyffert of Philadelphia. The presentation address was made by Dr. Lewellys L. Barker.

State Hospital Commission Abolished.—The Sage bill, legislating out of office the present State Hospital Commission and providing for the appointment of a single State Hospital Commissioner at $10,000 a year, passed the Senate last week.

No License for Christian Science Healers.—The New York Assembly has defeated the bill of Assemblyman Thorn which would have exempted Christian Science healers from the medical practice act requiring the examining and licensing of physicians. The vote was 46 for the bill to 79 against. A similar bill last year passed both the Senate and Assembly, but was vetoed by Governor Glynn.

New York City Death Rate.—There were 1,934 deaths in this city during the week ending April 10, an increase of 103 over the preceding week. This rise is attributed to the prevalence of influenza causing an increase in respiratory diseases. The death rate for the first fifteen weeks of this year was 14.57 per thousand of population as compared with 15.50 for the corresponding period in 1914.

Health of the Canal Zone.—The February report

of Dr. Charles F. Mason, chief health officer of the Canal Zone, states that there were nineteen deaths from all causes among the employees in the Canal Zone during the month. Of these nine died from disease, or 3.15 per thousand, as compared with 4.38 for the preceding month, and 5.34 for the corresponding month of last year.

An Impostor.—Physicians are warned against a man at present or lately traveling through the middle West, who represents himself as an agent of the Victor Electric Company and after gaining the confidence of his victim induces him to cash a check which turns out to be worthless. Any one learning of the man's whereabouts is requested to telegraph (collect) to the company's office in Chicago.

Reappearance of an Old Friend—After a silence of eight months the *Progrès Médical* of Paris has resumed publication, the first issue being dated August, 1914—March, 1915. For the present the journal will appear as a monthly, the weekly publication being deferred until tranquillity is re-established.

"American Journal of Surgery."—The March number of this interesting journal is entirely devoted to the subject of fractures; and is also noteworthy in that it marks the completion of ten years of publication under the present highly efficient editorial and business management. Contributors of original articles include: Sir W. Arbuthnot Lane, and Drs. Albee, Darrach, Walker, Zimmermann, Cotton, Downey, Estes, Pirrung, Ashhurst, Young, Lilienthal, Moorhead, and Marcy. As would be expected with this array of talent, this symposium is one of great value to the general practitioner, who is usually the first to see fracture cases, as well as to the surgeon.

The New York Polyclinic Medical School and Hospital has recently received an endowment of $50,000 by the will of the late Mrs. Mary Anna Palmer Draper, and $10,000 as a gift from a member of the Board of Trustees of the institution.

Dr. Herman Grad has been appointed attending surgeon to the Woman's Hospital, New York.

The National Commission of Milk Standards will hold its annual meeting in New York City on May 7 and 8.

Beriberi on a German Warship.—The *Kronprinz Wilhelm*, the German converted cruiser which sought shelter in Hampton Roads, Va., on April 11, had 63 cases of beriberi among her crew and 31 cases have developed on board since that time.

In Aid of Cancer Research.—At a meeting of the Harvard Overseers on April 14, announcement was made of gifts and legacies amounting to $72,908 to be devoted to cancer research at the Harvard Medical School.

The American Medico-Pharmaceutical League.—The eighteenth annual convention of this Society will be held at the Hotel Astor, New York, on Monday evening, May 24. Persons desiring to read papers at this meeting are requested to send the titles of the same to Dr. Samuel F. Brothers, chairman of the executive committee, 96 New Jersey Avenue, Brooklyn, N. Y. Members of the New York State Medical Association, of the State Dental Association, of the State Pharmaceutical Association, and other non-members of the American Medico-Pharmaceutical League, are invited to attend and to present papers.

Charitable Bequests.—By the will of the late Marcus Katz of Philadelphia, the sum of $200 is bequeathed to the Jewish Hospital of that city.

By the will of the late Edward Dale Toland of Philadelphia the sum of $5,000 is bequeathed to the Chestnut Hill Hospital and $1,000 to the Children's Hospital.

By the will of the late Matthias B. Colton, of Philadelphia, the sum of $1,000 is bequeathed to the hospital of the University of Pennsylvania for the maintenance, housing and enlargement of the social service of the out-patient department.

Association for the Study of Epilepsy.—The National Association for the Study of Epilepsy and the care and treatment of epileptics will hold its fourteenth annual meeting at the Hotel Chamberlin, Fortress Monroe, Va., May 10, 1915. Immediately following are the sessions of the seventy-first annual meeting of the American Medico-Psychological Association.

Dr. B. F. McGrath has resigned his position on the staff of the Mayo Clinic, Rochester, Minnesota, to take charge of the laboratories of pathological and surgical research in Marquette University, Wisconsin.

Dr. Philip J. Castleman has been appointed director of the bacteriological laboratory of the Boston Board of Health to succeed Dr. James J. Scanlon, who died a short time ago.

Dr. Andrew Hunter of the medical department of Cornell University has accepted an appointment to the chair of pathological chemistry in the University of Toronto.

The Late Dr. Joseph H. Raymond.—The Faculty of the College of the Long Island College Hospital has adopted a memorial minute on its late associate Prof. Joseph H. Raymond, Secretary of the Faculty, from which we select the following facts regarding a busy professional life: Dr. Raymond was born in Brooklyn, N. Y., November 18, 1845. He received his preliminary education at the Brooklyn Polytechnic Institute and was graduated from Williams College in 1866, receiving his A. M. degree three years later. He was a graduate in medicine of the Long Island College Hospital in 1868 and of the College of Physicians and Surgeons in New York in the following year. After graduating in medicine he served on the staff as interne of the Nursery and Child's Hospital and of the Idiot Asylum on Randall's Island, and subsequently in the Brooklyn Hospital. He spent several years in general practice, but his taste led him to devote all his time to the teaching of physiology and sanitary science and so to further the interest of the community in preventing rather than curing disease. He was for many years connected with the Health Department as Sanitary Inspector, Sanitary Superintendent, Deputy Commissioner and Commissioner of the Brooklyn Board of Health. Dr. Raymond filled the position of secretary of the faculty of the Long Island College Hospital for nearly thirty years. It was at his suggestion that the late Mrs. Theodore Polhemus, when generously donating a fund for the erection of the Polhemus Memorial Clinic in memory of her husband, added to the clinic building sufficient space to be used for the instruction of students; so that the college has, through Dr. Raymond's foresight, a structure that is admirably equipped for both teaching and clinical work. Besides his work in and for the Long Island College Hospital, Dr. Raymond was interested actively in general and medical education as a trustee of the Brooklyn Polytechnic Institute, a director of the Brooklyn Eye and Ear Hospital, editor for several years of the *Brooklyn Medical Journal;* au-

thor of "History of the Long Island College Hospital and Its Graduates," and a standard work on physiology, as well as numerous papers on medical and sanitary subjects. He served as secretary and treasurer of the Hoagland Laboratory and secretary of the Polhemus Memorial Clinic. He was at one time medical examiner for the New York Board of Education. He was a member of the Medical Society of the County of Kings, New York Physicians' Mutual Aid Society, vice-president of the American Public Health Association, and visiting physician, St. Peter's Hospital. Personally Dr. Raymond was a charming companion and associate —alert of body, quick in thought, word and action. He thought the present times were better than the past and the future times would be better than the present. Courteous and considerate of one's feelings, he endeared himself to the students of the college and all of the members of the faculty who have for so many years been associated with him.

Obituary Notes.—Dr. JULIUS MOUNT BLEYER, of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1883, and an LLD. of Central University of Indiana, the originator of the present method of electrocuting criminals in New York State, vice-president of the American Congress on Tuberculosis, 1901-04, a fellow of the Royal Academy of Medicine and Surgery of Naples, Italy, a corresponding member of the National Academy of Medicine of Mexico, a former fellow of the American Medical Association, and a member of the American Association for the Advancement of Science, the American Academy of Political and Social Science, and the Medico-Legal Society, of which he had been vice-president since 1903, died at his home, on April 3, aged 56 years.

Dr. HENRY OSTHUES of Brooklyn, N. Y., a graduate of Niagara University, Medical Department, Buffalo, N. Y., in 1894, died at his home on April 4, aged 46 years.

Dr. JAMES GUYON CLARK of West New Brighton, Staten Island, New York, a graduate of the College of Physicians and Surgeons, New York, in 1845, formerly physician to Bellevue Hospital and attending physician to the Home for Destitute Seamen, Snug Harbor, and a member of the New York State and Richmond County Medical Societies, died at his home on April 9, aged 90 years.

Dr. ERNEST PENDLETON MAGRUDER of Washington, D. C., a graduate of George Washington University, Department of Medicine, in 1902, clinical professor of surgery at the Georgetown University School of Medicine, Washington, and a member of the American Medical Association, the Medical Society of the District of Columbia, the Surgical Society of Washington, and the American College of Surgeons, died at Belgrade, Serbia, from typhus fever, on April 8, aged 40 years. Dr. Magruder went to Serbia a short time ago with one of the Red Cross units, and is the second American surgeon to fall a victim to the disease, the death of Dr. James F. Donnelly of Brooklyn having been reported a few weeks ago.

Dr. WILLIAM C. CROOKS died at Philadelphia on March 14 at the age of 65 years as a result of an apoplectic seizure. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1866.

Dr. JULIUS PAUL LAUER died at Philadelphia on March 16 at the age of 36 years, as a result of an attack of typhoid fever. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1908. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. HENRY WALBANK JONES, formerly of Houghton, Mich., a graduate of the Rush Medical College, Chicago, in 1876, died at the home of his daughter, in Short Hills, N. J., on March 21.

Dr. STEPHEN BENJAMIN MUNN of Waterbury, Conn., a graduate of the Georgia College of Eclectic Medicine and Surgery, Atlanta, in 1882, and of the Bennett Medical College, Chicago, in 1888, died at his home on March 22, aged 88 years.

Dr. PHILIP M. WOOD of Jamaica, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1876, surgeon to St. Mary's Hospital, Jamaica, and a member of the New York State and Queens-Nassau County Medical Societies, the Greater New York Medical Society, and the Associated Physicians of Long Island, died at his home on March 27, aged 60 years.

Dr. GEORGE S. CHALMERS of Galesburg, Ill., a graduate of the Physio-Medical Institute, Cincinnati, in 1878, a member of the Illinois State and Knox County Medical Societies, and for twenty years coroner of Knox County, died at his home on March 11, aged 69 years.

Dr. CHARLES JEWETT LINCOLN of Augusta, Me., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1895, and a member of the American Medical Association, the Maine Medical Association, and the Kennebec County Medical Society, died at his home, after a short illness, from blood poisoning, on March 14, aged 46 years.

Dr. TRISTRAM ROGERS of Plymouth, N. H., a graduate of the Worcester, Mass., Medical College, Eclectic, in 1855, died at his home, after a long illness, on March 18, aged 81 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR AND INCREASED COST OF VARIOUS MATERIALS—SHORTAGE OF DRUGS FEARED AND HIGHER PRICES OF SOME—GOVERNMENT CIRCULAR ON PREVENTING DECREASE OF SUPPLIES—EXAMPLES.

LONDON, April 2, 1915.

"THINGS are so dear," "the price of everything has gone up." These are phrases heard every day, in all directions about anything or nothing. It is true of most things and usually is put down to the war, which is certainly accountable for many. But one would scarcely have anticipated that the cost of drugs would generally be raised from the same cause. A diminished supply of those usually imported from countries affected by the conflict is natural enough, and such as are almost exclusively manufactured in such countries have been steadily approaching a state of scarcity. You will probably feel something of this on your side, especially as to those for the supply of which you have depended on Germany. The blockade, unless made a farce by our inefficient government must certainly interrupt to some extent the supply. Some drugs here are now six or seven times as costly as before the war and many are double, treble, and quadruple the former price. The advance in acetylsalicylic acid at the beginning of this week had been to seven times, and probably may not be limited to that. Acetanilid and phenacetine are quoted as only four times

more than the usual price, phenazone double. Salol and all the other salicylates are of course greatly involved. As to carbolic acid there is not only the demand for it at the front and in the army hospitals, but its necessity for the manufacture of lyddite. Another important drug in extra demand is opium and its chief constituent morphine, but though the price is on the rise it will not be likely to be excessive as India can furnish a supply, though it does not contain so large a percentage as the Turkey variety. The bromides and chloral hydrate are also twice as dear as formerly, apparently from scarcity. This has been the cause suggested for atropine advancing, but it seems very uncertain. The same may be said of many other drugs, but as to not a few there seems no reasonable explanation. English manufacturers have now an excellent opportunity of establishing their ability to produce alkaloids and other chemicals, but probably with their usual apathy will let it slip.

The Government issued a "confidential" circular to the medical profession on the supply of drugs as affected by the war, with some suggestions for economy which give rise to some criticism but seem generally to be received favorably. It is not the first communication of the kind from the Government, which last August appointed a committee of medical men to consider questions connected with the supply of medicaments, especially as to any of which the war had produced a shortage. Under the advice of that committee, which consisted of men in whom the profession has confidence, a circular was issued containing suggestions which have been generally accepted as measures which could be adopted by practitioners in order to prevent the stocks of those drugs which were getting small becoming exhausted. Since August the situation has undergone many modifications. Hence the issue of this new circular, which is intended to supersede its predecessor. It is not to be supposed that the medicaments named are so scare as to be withheld when they are really needed, but that in numerous cases there are efficient equivalents.

Carbolic Acid.—In view of the great demand for war purposes practitioners are invited to be as sparing as possible for other uses. For numerous cases cresol preparations are good substitutes, *e.g.* liq. cresoli sap. B.P., an excellent official preparation hardly yet enough appreciated; I would also mention hydrag, perchlor, and biniod., tincture of iodine, peroxide of hydrogen, etc.

The Salicylate Group.—It is suggested these might be restricted to acute rheumatism and its complications. I certainly agree that this is only reasonable; for in other cases in which it is often used it cannot be said to have much claim.

Local Anesthetics.—Novocaine, eucaine and compounds of them require the greatest economy.

Atropine.—As much or more may be said for this and it should only be used when definitely needed.

Thymol should be sparingly prescribed. Other antiseptics are just as good or better than it for mouth washes, gargles, etc., *e.g.* peroxide of hydrogen.

Wool Fat.—Lanoline and ointments made with wool fat should be substituted by others unless definite advantage is expected from it.

Paraldehyde is chiefly used in asylums and their medical officers are sure to act as the circular suggests. Phenazone, phenacetin, if useful as analgesics, are of little if any use as antipyretics, and for such use may well be discarded.

Progress of Medical Science.

1. The Patriotic and Humane Service of the Red Cross Nurse. Miss Mabel T. Boardman.
2. A Report on Some Cases of Perineal Prostatectomy. F. G. Balch.
3. On the Fixation of Fractured Bones in Infants and Young Children. E. H. Bradford and R. Soutter.
4. Border-Line Cases of Mental Defect with Special Reference to Hysterical Symptoms. C. C. Beckley.
5. Somatic Characteristics of General Paretics. D. Gregg.

2. Perineal Prostatectomy. — F. G. Balch reports the results obtained in twenty-eight cases in which this operation was performed by him at the Massachusetts General Hospital. There were two deaths, one from peritonitis caused by perforation of the sigmoid, probably by a rectal tube. In these cases spinal anethesia was used, excepting in four instances, when ether was employed. One of the advantages of spinal anesthesia is the fact that the patients are old in whom it is desirable to avoid irritation of the bronchial mucous membrane. Another advantage is the fact that the patient can drink water immediately after the operation. Drainage tubes were removed usually on the second day. Hemorrhage was a negligible factor.

3. Fixation of Fractured Bones in Infants.—E. H. Bradford and R. Soutter allude to the difficulties of securing fixation of fractures in infants and young children. These are particularly evident in the case of fractures of the upper third of the thigh. The authors describe a method of fixation which they have employed in fractures of the upper arm and of the femur. It is as follows: By means of a long bone drill, with an eye at the point, the broken bone is pierced and strong 30-day catgut threads passed through the eye of the needle thrust through the skin. On withdrawing the needle the catgut is pulled through the bone. No dissection is necessary as the bone drill is readily thrust through the skin down to the bone. Palpation and the skiagram are sufficient guides for the proper placing of the catgut in the fragments of the bone. Any needed number of catgut cords can be passed. The skin is protected by a layer of fat-free leather, which will soften when wet and harden rapidly into stiffness. This leather soaked in alcohol is sterilized, and placed around the limb and the catgut threads passed through it. Small wood coaptation splints are then placed in desired places pressing on the side of the limb, one to check a forward and backward movement of the fragments, and another to prevent sideplay. Traction is then applied to the limb, the coaptation splints held in position, the catgut threads passed through the fractured bone are tied to the coaptation wood strips, thus firmly lashing the fragments in proper position to a firm splint; over the whole a second layer of alcohol softened leather can be placed, held by a firm bandage, and the limb secured in a wire splint. The leather softened in alcohol hardens quickly on the evaporation of the alcohol and in a short time the fractured limb is held in a firm leather splint. The position can at any time be determined by a skiagram. In the cases (young children) in which the method was used the leather splints and wood side splints were removed in four weeks, the catgut having softened and the fracture being firmly healed. The treatment involved no more complication than in the simple method formerly used, while a proper alignment of the fragments was secured without delaying the functional activity of the limb.

4. Borderline Cases of Mental Defects.—C. C. Beckley describes a series of these cases which have

certain qualities in common. First, they are all delinquents. They have been judged and committed as such by the courts. Second, they are only partially responsible for their acts, and have no relatives or friends who are able to control them. Third, the hysterical symptoms, the exaggeration of symptoms due to physical defects and the simulations of disease oftentimes increase their inability to compete with other more fortunate individuals in earning a living. These patients are a prolific source for the spread of venereal diseases. They do not belong in a reform school, as they cannot be reformed. They upset the discipline, and are a detriment to the best interests of others who can be helped. They do not, as a rule, belong in an insane hospital or a feeble-minded school. The expense of proper custodial care would be much less to the State than under the present unsatisfactory system when one considers the time taken by the courts, probation officers, police, their intermittent control in more expensive State institutions, etc. Custodial care is demanded for the more definite cases of this type.

5. **Somatic Characteristics of General Paretics.**—D. Gregg notes that there is considerable evidence to show that individuals of the so-called carnivorous type are particularly susceptible to diseases of the nervous system. In a study of 100 cases, diagnosed clinically as general paresis, among whom 81 showed a positive Wassermann reaction in the spinal fluid, and the remaining 19 a positive Wassermann reaction of the blood, while the spinal fluid was suggestive or untested, the hypothesis that these cases were of the carnivorous type was supported by the fact that 83 per cent. of them were Northern races; 68 per cent, normal or above normal in height, and 82 per cent. averaged 23.1 pounds subnormal in weight. The hitherto unexplained discrepancy between the many cases of syphilitic infection and the small percentage of syphilitic individuals developing general paresis, may be explained, not on the hypothesis that there are varying strains of spirochetes, or coincident environmental strains, alcohol or other intoxicants, but that only a certain type of individual is susceptible to syphilis of the nervous system.

8. The Normal Nasal Septum and the Pathology of Deflections. F. O. Lewis.

1. **Trials and Triumphs of the Surgeon.**—J. Chalmers Da Costa discourses upon this subject in a witty and epigrammatic vein. He quotes Paget's figures, which show that almost one-third of any class of students make a mistake when they select medicine for a profession, and is disposed to believe that Paget's estimates apply today. It is vastly to the credit of the profession that few leave it to go into quackery. Vanity is one of the most potent causes of failure. The vain man in surgery is a deadly peril. Real success comes only from persistent hard work. Some of the apothegms, aphorisms and epigrams that have crystallized in the mind of the author are the following: Many a man who is brooding over alleged mighty discoveries reminds one of a hen sitting on billiard balls. A fashionable surgeon, like a pelican, can be recognized by the size of his bill. Diagnosis by intuition is a rapid method of reaching a wrong conclusion. A man who pays his surgeon many gleaming compliments seldom pays him anything else. The public has an idea that a consultation is a meeting of accomplices. The first patient the author ever had stole his only umbrella.

2. **The Colloidal Gold Test on Spinal Fluid.**—C. J. Swalm and A. L. Mann have found in their work with psychiatric cases that all reacted to the extent of one or two plus in the first tubes, and hence no reaction less than three plus or dark blue was recorded as positive. In paresis, the test is of great value in diagnosis, at least ninety per cent. of the cases providing the typical curve, the true specificity of which the authors doubt. The goldsol test should be used in conjunction with the serum and spinal fluid Wassermann reaction, globulin tests, and cell count, as a more delicate method of interpreting their results and to correct them when they fail. The authors' cases of tabes furnished a marked luetic curve in fifty per cent.; the cases of cerebrospinal syphilis in sixty per cent. Nonluetic psychoses produce weak reactions, without characteristic curves.

3. **The Ataxia of Tabes.**—M. Grossman notes that the clinical observations made by most writers reporting the effects of blindness on the ataxia of tabes, and the results obtained in these and other cases treated along the same lines, show the rationality of reeducating ataxic tabetics blindfolded. By this method of treatment, one rapidly increases the actual coordinating power of the patients. The psychic components of ataxia, such as fear and fatigue, are decreased. Hope and confidence are instilled into a class of patients who heretofore have received little or no encouragement.

4. **Treatment of Puerperal Sepsis.**—R. T. Frank states that in most cases a rise in temperature in the puerperium is transitory and of little significance. Many a light infection is converted into serious or fatal disease by meddling. If the patient shows signs which might be interpreted as infection—fever, rapid pulse, malaise, etc., the breasts should be examined for induration, the kidneys palpated for signs of pyelitis, and the urine examined for pus. The patient's chest is gone over, the amount of lechia determined, the bowel function inquired into. The genital tract is not examined for one knows that the uterus is empty. At the most, one carefully inspects a sutured perineum to see that signs of infection are absent. Should local tenderness, a drop of pus along a stitch hole and edema be present, all perineal sutures are removed; the wound is opened, touched up with half strength tincture of iodine, and lightly packed with iodoform gauze. If no improvement occurs, one does not irrigate the uterus to combat retention, or curette away the protecting granulation tissue, and occluding placental thrombi. One does not grasp the cervix and pull it to the outlet, breaking up delicate adhesions around the tubes and ovaries which encapsulate a forming tuboovarian abscess. One should wait for distinct signs, for local symptoms which require interference. The intervening time is, however, well spent. The general condition is improved by open air (roof) treatment, by careful attention to the diet (easily digested, nutritious), by keeping the bowels and kidneys active. Involution is assisted by small, repeated doses of ergot, and as long as the fundus is palpable above the promontory, by an ice bag and the Fowler position. Should stimulation be required, drugs such as caffeine, camphor, and digitalis are used. Quiet and sleep are induced by hypnotics, and pain is combated with ice bag, codeine, or morphine. Should local symptoms develop, these are dealt with only as they arise.

Pus foci, such as pelvic abscesses, abscess above Poupart's ligament, or even tuboovarian abscesses are merely drained when they distinctly "point." Phlebitis in the lower extremities is treated by immobilization, elevation of the limb, and absolute quiet. Even pelvic phlebitis the author does not attempt to cure by abdominal section and ligation of the veins. When blood culture shows a bacteriemia, the waiting policy is equally effective. Virulent cases of streptococcemia, which are usually fatal within two to three weeks, may be given a polyvalent antistreptococcus serum, which sometimes, though rarely, helps. Staphylococcus and colon infections are frequently cured after a more or less protracted illness, during the course of which metastatic abscesses, in distant organs (kidney, muscles, eye) may require incision. In those cases in which exudates develop around the uterus recovery almost invariably follows. Pelvic abscesses are common sequelæ. In cases admitted to the hospital or seen in consultation, in which the conduct of the labor, especially the complete expulsion of the placenta, is in doubt, the temptation to explore the uterus is almost uncontrollable. Unless the size of the uterus is unmistakably far greater than that warranted by the number of days elapsing since labor, this organ should be left untouched. Only if very great disproportion exists, indicating retention of the greater part of the placenta or the presence of a fibroid is very gentle digital exploration permissible.

8. Deflections of Nasal Septum.—F. O. Lewis calls attention to three forms of deviation, which have been forcibly impressed on the author because of the local and constitutional symptoms they produce, the difficulty often encountered in their correction, and the gratifying results obtained after operation. First, a deviation of the quadrilateral cartilage caused by injury, in which the cartilage has been fractured or dislocated in such a manner that the convexity of the deformity obstructs one side of the nose; and the free border of the cartilage, projecting into the opposite nostril, partially or completely obstructs the other side, with perhaps a compensatory hypertrophy of the inferior turbinate, which adds to the discomfort of the rhinologist as well as of the patient. To correct this, the entire cartilage, especially if there is a twisting of the tip of the nose, has to be removed; and this is one type of cases in which the author has had excellent results in the transplantation of cartilage. The second type of deflection is usually found near the floor of the nose, extending from within the vestibule of the nose to almost the posterior nares, comprising both cartilage and bone, with overlapping of each and a groove on the opposite side, impinging against the inferior turbinate, interfering with drainage and ventilation, and associated with Eustachian catarrh and subsequent deafness. The third type of deflection is that of the vertical plate of the ethmoid, impinging against the middle turbinate, which may be hyperplastic, giving rise to such reflex symptoms as hay fever, asthma, headaches, neuralgic pains about the face, and cough.

1. The Schick Reaction.—H. N. Bundesen concludes that by means of the Schick test one is in a position to tell definitely who are susceptible to diphtheria, and when an epidemic breaks out one can inject those and those only, paying no further attention to the ones giving a negative reaction. By it the danger of cross-infection is greatly decreased. Children with diphtheria that have had scarlet fever and are therefore immune to scarlet fever can be placed in scarlet fever wards when the inmates yield negative Schicks, etc. The reaction permits a great reduction in antitoxin bills. Much needless pain and annoyance of patients is avoided, and the possibility of anaphylactic shock is greatly minimized.

3. The Intradermic Diphtheria Toxin Test.—E. E. Moody finds the test is of definite value in enabling one to differentiate between persons who are susceptible to diphtheria and those who are not susceptible, and is therefore useful in determining which cases, of those to be placed in an environment where the liability to exposure is great, should be immunized. It is of value in the differentiation between clinically doubtful cases of diphtheria, positive reactions being obtained in clinical cases and negative reactions in carriers. It is useful in experimental work in determining the effects of various forms of immunization and the duration of immunity conferred by these methods. It has a definite value in the handling of diphtheria epidemics in institutions.

4. The Superstition of Flat Foot.—R. W. Lovett states that feet vary in shape as much as do our features; some are naturally flat, others have a moderate arch, and some a very high arch. Any foot may become painful from foot strain without any change in the height of the arch under unfavorable general conditions, overuse, ill health, etc. Boots are a predisposing factor to foot strain not only by cramping the foot, but especially by not supplying adequate support to the sole of the foot. For this reason persons with high arches are quite as liable to foot strain as persons with low arches, if not more so. When foot strain occurs, it is desirable to rest the tired structures by support, most often a metal plate. Exercises in acute cases and the use of a flexible shoe generally do harm rather than good. The author's final heresy consists in the belief that painful feet are more often helped by raising the heels than by lowering them.

8. Pituitary Extract in Obstetrics.—J. K. Quigley concludes that pituitary extract is the most powerful stimulant to uterine contraction yet discovered. Its greatest value is its use in uterine inertia. The ideal time for its exhibition is in the second stage, although good results follow its employment earlier; in these cases it is usually necessary to repeat the dose. No untoward results, such as postpartum hemorrhage or asphyxia were noted for mother or child in the author's

fifty cases. The drug shortens the third stage. It renders catheterization postpartum almost never necessary. It has no place in the normal case. Preparations for delivery should be made at the time of injection, such as sterilizing hands and gloves. The facilities for giving an anesthetic at a moment's notice are prerequisite, for one does not know the susceptibility of the uterine muscle in any particular case. Pituitary extract may advantageously be supplemented by seminarcosis when the presenting part is on the perineum. (This would naturally mean chloroform, ether, or pituitary extract. Nitrous oxide is contraindicated in scopolamine narcosis.) Pituitary extract must be used judiciously and with a due appreciation of the possible dangers of so powerful a uterine stimulant. This is the most important point.

10. The Spinal Fluid in Pneumonia.—G. L. Rohdenburg and A. Vander Veer, Jr., point out that pneumococci are present with much greater frequency in the spinal fluid than is usually thought to be the case without the presence of meningeal symptoms. The early lysis of pneumococci, with the liberation of the endotoxin and its close proximity to vital centers, may well explain the profound and sudden cardiovascular collapses, as well as the marked mental symptoms so often noted. Of good prognostic import are a negative blood culture, a negative spinal fluid culture, a falling curve of leucocytosis, and a maximum temperature on the third day. On the other hand, the finding of pneumococci in the spinal fluid and blood, a maximum temperature on the fifth day, an irregular leucocyte curve, with a maximum on the third day and a steadily falling blood pressure, are indications of a fatal termination.

11. The Autoserum Treatment of Skin Diseases.—M. L. Ravitch believes that autoserum is not an ideal or an effective remedy in skin diseases. It has been found by him to be ineffective in urticaria and chronic eczema. It gave striking results in a very obstinate case of psoriasis of thirty-two years' duration. Sixty per cent. of the cases of psoriasis did not respond at all to autoserum, while the rest of the subjects were benefited only temporarily. The author had as good temporary results from lecithinized serum, plain artificial serum, and injections of cacodylate of soda and mercury. In psoriasis none of the serums made any impression on the disease without the use of chrysarobin. Urticaria and pruritus were not materially benefited by serum of any kind. This is attributed to the fact that urticaria and pruritus are in all probability due to some focal infection or internal metabolistic disarrangements. A judicious and careful use of chrysarobin externally, with the employment of a suitable drug internally, is as efficient as the autoserum therapy.

12. Mushroom Poisoning.—M. Clark, C. K. Marshall, Jr., and L. G. Rowntree report a case of amanita poisoning in which the nervous and mental symptoms, which were pronounced and which are not infrequently present in this type of poisoning, accompanied renal insufficiency, and may well have been uremic in nature. Heretofore, the tendency has been to ascribe such symptoms to the influence of some peculiar "neurotoxin" of the fungus. Renal functional studies will probably prove these symptoms to be uremic in character.

1. The New Psychiatry.—W. H. B. Stoddart in the third of the Morison Lectures discusses various matters that have been elucidated by psychoanalytic methods respecting the neuroses, psychoneuroses, and psychoses. Freud recognizes two neuroses proper—viz., neurasthenia and the anxiety neurosis. Probably a few cases of hypochondriasis are due to the same etiological factors as these neuroses and should therefore be included in the same group. The term "neurasthenia" is now limited to a class of cases which exhibit very definite symptoms, the chief of which is an undue tendency to fatigue. In all cases of this kind, without exception, there is always to be found one essential etiological factor—viz., sexual excess. In the majority of cases this takes the form of masturbation, but in a few patients the disease is traceable to frequent nocturnal pollutions. Freud and all who have subsequently investigated the matter are agreed that the anxiety neurosis owes its origin to an accumulation of mental excitement which finds no somatic outlet, and further, that this excitement is almost always, probably always, of a sexual nature. Accordingly one meets with this neurosis among engaged couples who cannot afford to get married, in widows and widowers, in women whose husbands practise coitus interruptus (this is the commonest cause), in women during the climacteric whose husbands have reached senility, and in patients who with great effort have renounced masturbation. Since the advent of the new psychiatry many patients have been analyzed by modern psychological methods and the outcome has been the remarkable discovery that paranoia is a psychosis erected on the invariable basis of repressed homosexuality. Naturally enough the idea that a person has homosexual inclinations is usually repugnant to him; he refuses to admit it to himself, and it is repressed into the unconscious. Should such repression fail, the homosexual complex reappears in consciousness in the disguised form of paranoia or as dementia paranoides, for it has been shown that the same psychical mechanism is at work in this variety of dementia præcox, designated by Kraepelin in his most recent edition as "paraphrenia."

7. Autogenous Vaccines in Pneumonia.—Nathan Raw states that during the last five years he has treated in hospital and elsewhere 310 cases of pneumonia with vaccine, with 42 deaths, or a mortality of about 13 per cent. In many of these cases vaccine was administered on the second or third day of the disease, and was given every four hours or at longer intervals, according to the severity of the case, and although the results have not always come up to the author's hopes and expectations he has never once observed any unfavorable symptom follow the use of vaccine in whatever dose it has been administered. The much debated question as to whether or not a vaccine should be given in the course of an acute infective disease must, in the author's opinion, be answered in the affirmative, and during a recent visit to France he was much interested to find that acute cases of typhoid fever with high temperature were being treated with antityphoid vaccine with excellent results.

8. Notes on Two Cases of Angioneurotic Edema. F. L. Davis.

1. Acute Appendicular Obstruction.—S. T. Irwin concludes that acute diseases of the appendix may be divided into two classes—acute appendicitis and acute appendicular obstruction. To the latter class belong most of the tragedies of abdominal surgery. Safety lies only in the way of early operation—that is, before perforative peritonitis has supervened upon distention and gangrene of the appendix. Lastly, what of the third day in acute diseases of the appendix? Let us blot it out altogether, and rename it the first day—after operation!

2. Autogenous Living Vaccine in Treatment of Typhoid Fever.—E. A. Bourke, I. D. Evans, and S. Rowland having recently treated cases of enteric fever with vaccine and obtained satisfactory results, it occurred to one of them (S. R.) that better results might be obtained by employing autogenous living vaccine for each case. The clinical notes and temperature charts of the first successive cases treated by this method and the satisfactory results obtained suggest that the procedure will be given a more extensive trial. This method of injecting living bacilli in suitable doses is perfectly safe. The vaccine was injected subcutaneously—as a rule in the pectoral region—and was followed by very slight local reaction, but marked general reaction. No local or general complications were observed. The injection, as a rule, was followed by a rise in temperature within the first few hours, followed by a marked fall within twenty-four hours of inoculation. Careful notes were made, and in the authors' minds there is no doubt that this treatment had a beneficial effect and tended to cut short the duration of the disease. It promotes perspiration, the aspect of the patient becomes brighter after injection, and the tongue becomes much cleaner. The diagnosis was verified in all cases by blood culture. Several of the cases on admission to hospital gave the impression that the attack would be severe. The disease was in each case diagnosed by means of blood culture. For this purpose 5 c.c. of blood were drawn from the arm and immediately transferred to 1 per cent. sodium taurocholate. From this a broth culture was prepared, and the purity and identity of the growth verified by agglutination and sugar fermentation tests. The broth culture was reinoculated into fresh broth every day and itself constituted the vaccine. No further preparation whatever was employed. The age of the culture used was generally eighteen hours, and the number of bacilli contained in it was obtained by a direct method of counting which has been previously described by one of the authors. The average number of organisms ranged from 60 to 300 millions.

7. Treatment of Dry Pleurisy by Temporary Partial Artificial Pneumothorax.—G. Lucas reports a case which illustrates the benefit which may be derived from temporary separation of the two inflamed surfaces of pleura in a case of long-standing dry pleurisy by a layer of nitrogen, which in this way acts as a pneumatic splint, by means of which the inflamed parietal and visceral pleura may be put at complete rest, and conditions are produced under which repair and recuperation may be brought about—a condition which is not allowed them by Nature whilst they are in actual apposition. The length of time for which the so-called splint may be applied may be regulated by the requirements of the case.

March 11, 1915.

Rabbits for Human Consumption.—Schottelius states that rabbit flesh has of late been repeatedly suggested as a dietetic article for man; the impression having got abroad that it is cheap and nutritious. That they cost little to raise is a mistake. They eat more food values, pound for pound of body weight, than cattle and much more than swine. A hog will utilize twice as much fodder and will also eat waste materials. An experiment was conducted some years ago on the wholesale feeding of rabbits with garden vegetables and waste products, which proved a failure. A survey of the industry in raising Belgian hares in Belgium and France shows that the "giant hare," "butcher's hare" (or whatever else it is termed) consumes an enormous amount of fodder, while a female bears 50 young per annum. Hence one rabbit and her brood must, in order to thrive eat an enormous amount of vegetable food. If a hare with a "live weight" of 500 gms. is slaughtered it will weigh but 200 gms. after the heavy skin and intestines are removed. The pale glassy flesh has to be seasoned highly to make it palatable. But rabbit culture should not be abandoned, because it furnishes the boy, who is as a rule a zoophile, an ethical training in caring for the animals, and further tends to dispel some of the monotony of existence.

Shot Wounds of Peripheral Nerves.—Kirschner sums up a long article as follows: not every bullet wound of a nerve leads to a loss of function. The clinical evidences (not always present) of a nerve injury comprise: 1, motor paralyses of different degrees. 2, sensory paralyses. 3, radiating pains setting in at once or gradually after the injury. 4, vasomotor and trophoneurotic disturbances. The pathological conditions encountered in operative exposure may show a nerve imbedded in scar tissue, a nerve in contact with an irritating foreign body, a nerve torn across or thickened (perhaps irregularly). Finally, despite functional disorders we may find no pathological lesion at all. Operative therapy should not be undertaken before the expiration of six weeks if motor paralyses are present. Every case of motor paralysis which has not improved by the end of this period, and all other cases which have become worse must be subjected to operative isolation of the nerve with special emphasis on those cases in which the suffering grows progressively worse. Operative procedures involved include mobilization and following suture of individual nerves; implantation of segments of some foreign material between the ends of a resected nerve, neurolysis in an intact nerve and the enveloping of all traumatized nerve tissue in a sound tissue.

Combat Against the Louse Plague at the Front.—von Marschalko proposes the revival of an old remedy for this condition, to wit: rectified oil of turpentine. This destroys not only all kinds of lice but vermin of all sorts—roaches, etc. It destroys them by suffocation, clogging the respiration passages. Its advantages which are numerous are also obvious. In fact it may be said to have no drawback, save its odor. Although it kills parasites through the entrance of its vapor into the breathing passages it is said to be able to destroy all nits. Expensive silk shirts do not protect the officers who wear them from the body louse. Anisol is far too expensive. To economize with turpentine it should be sprayed when possible. It may be diluted to some extent with alcohol.

Insurance Medicine.

Relations of Life Insurance Medicine to Medicine as a Whole.—Gottstein refers to Florschütz's recently published work on life insurance medicine (Allgemeine Lebensversicherungsmedizin) as one which contains much more information than its title indicates. Thus the highly trained and progressive physician of the present day should realize fully that life insurance medicine is founded solely upon the empirical teachings of its own records of past decades and hardly at all upon comparatively recent scientific developments like bacteriology. But insurance medicine is not of course antagonistic to scientific medicine, because for the most part the latter simply presents old facts in a new manner; while insurance medicine candidly admits that it would enter the experimental field, if this were economically possible, to a limited extent and along certain lines.

Life insurance medicine is justified by the results obtained. Moreover in some respects scientific medicine in its progressiveness has assumed views which tend to uphold the oldest dogmata of insurance medicine which still constitute its foundation. We refer to the subjects of constitution and heredity, or, in other words, predisposition, which for a long time was threatened outright by the avalanche of bacteriological teaching.

It must not be taken for granted that this apparent antagonism between empirical and scientific teachings is a thing of yesterday, for it was most rife during the years following the general introduction of antiseptic surgery, when there was little thought of the patient's physique as long as the operation was aseptically conducted. Since that period the pendulum has been slowly moving in the opposite direction, and the old views of diathesis and other constitutional anomalies now have a scientific foundation.

To-day life insurance medicine possesses a value not only for experimental research but for the practice of medicine as well, or, in other words, all these aspects of medicine react freely upon one another and they can therefore be employed to check one another up.

Life insurance medicine must in a still more important degree be regarded as a benefactress for it deals with subjects beyond the scope of mere experiment, such as body habitus in its relationship with heredity. Life insurance medicine also furnishes documents of the greatest value to anthropology and biometrics. Here it is on a plane with all other subjects which have to do with observation *en masse*, such as military medicine, school medicine, protection of nurslings, etc. Such studies are cognate also with hygiene, social medicine, and legislation.

The subject of medical statistics, without reference to life insurance medicine, is a special study which can be carried out on a large scale on nonselected material and should naturally bear out the truth of the lessons drawn from insured material. Hence it is not a matter of chance that the old work of Westergaard on Morbidity and Mortality, as well as more recent productions of the same sort, furnish data which are of great value for life insurance, while conversely the vast figures of insurance medicine are of the greatest value for the general statistician.—*Blätter für Vertrauensärzte der Lebensversicherung*, Vol. V, No. 6, 1914, and Vol. VI, No. 1, 1915.

Periodic Examination of Supposedly Well Persons.—In a paper read before the Kentucky State Medical Association at Newport, September 22-25, 1914, Dr. Eugene Lyman Fisk, director of hygiene, Life Extension Institute, dealt with the periodic examination of supposedly well persons, and stated that on the whole the plan had been well received the average man is a pretty decent fellow. The fact in such examinations should be to uncover the workings of the human body and to secure a complete picture of the mechanism and of the conditions under which it exists. The methods of the Institute are explained at length. Dr. Fisk summarizes as follows: "At first glance some of the figures I have quoted may seem depressing, and raise grave questions as to whether the race may not be on the downward trend. I think we should take the opposite and optimistic view. On the whole, the world as we view it in passing seems pretty good, and the average man is a pretty decent fellow. The fact that an ordinary group of people, at an average age of thirty, taken, not from a hospital, but from one of the leading institutions of the world, is found suffering from so many disabilities which can be corrected, checked, or cured, points a way to sensible, practical, and easy methods of distinctly raising the general level of the vitality and well being of the race, which so many people, even life insurance experts, have thought was a fixed and unalterable quantity. The study of eugenics, and the utilization of this science in a conservative, rational, and scientific way to neutralize any possible ill effect on society as a whole from patching up the congenitally defective, should, of course, go hand in hand with the work. It should be remembered, however, that while saving the unfit, we are also improving the so-called fit, which is a powerful influence in keeping ahead of the game. Indeed, if we have faith in medical science we are able to see a vision of the superman, not as Nietzsche conceived him, a ruthless overlord, but as Bayard Taylor viewed him, gentle, as well as daring; tender, as well as brave. Let us look, then, not upon the dark picture of present degeneration, but upon the bright picture of future regeneration made possible by an intelligent and determined use of a larger and more accurate knowledge of man's weakness and capacity for wrong doing.

An Insurance Company's Mortality Experience from Pulmonary Tuberculosis, 1889-1913.—Dr. W. Perry Watson read a paper on the above subject at the 148th annual meeting of the Medical Society of New Jersey, at Spring Lake. He points out that the Prudential Insurance Company of America issues life insurance on healthy residents of the United States and Dominion of Canada, under two distinct methods, the industrial or weekly payment plan on lives, ages 2 to 65, and the ordinary or old line plan, premiums payable annually on lives ages 12 to 66. This paper considers only the latter plan. It appears that in the period noticed there were 40,938 deaths from all causes, of which number 7,706—18.8 per cent.—were from consumption. Of males there were 6,283 deaths from consumption—18.8 per cent. Of females there were 1,423 deaths from consumption—18.9 per cent. The largest number of deaths of males from consumption—1,237—occurred in the age period 30 to 34, giving a percentage of 19.7, that being the highest percentage according to age distribution, while the highest percentage of deaths of females—26.3—occurred in the age period 25 to 29.

Book Reviews.

CANCER, ITS CAUSE AND TREATMENT. By L. DUNCAN BULKLEY, A.M., M.D. Senior Physician The New York Skin and Cancer Hospital, etc. Price, $1.50 net. New York: Paul B. Hoeber, 1913.

IN the work before us Dr. Bulkley considers cancer, not from its histological and surgical aspects, but from the dietetic and medical treatment points of view. The author states, and his statements are based upon a long experience, that patients suffering from cancer rarely if ever receive continuous medical care before operation with the object of discovering and rectifying the cause of the morbid growth. Furthermore, after an operation, so far as his observation goes, the patients are almost invariably left entirely to their own resources with the hope that the tumor will not regrow, but with no attempt so to guide the life that there shall not be the same tendency to a recurrent malignant new formation.

In the chapter dealing with the relation of diet to the incidence of cancer a strong case is made out against overeating and especially against the undue consumption of meat as causes of cancer. In fact, in the opinion of the writer, a highly civilized luxurious life very strongly predisposes to cancer, while per contra a simple sparse diet is to some extent a safeguard against the disease.

With regard to the medical treatment of cancer Bulkley agrees with Sir Arbuthnot Lane that one of the terminal results of intestinal stasis may be cancer, indeed, he is strongly inclined to believe that the toxins produced by the millions of microorganisms generated through intestinal stasis and fecal putrefaction are the real predisposing causes of cancer, and therefore he recommends a purely vegetarian diet. The medical aspects of cancer are discussed fully. In these days of surgical dominance, when operation is urged for every growth or blemish that one chooses to call "precancerous," it requires courage to call for delay, to ask the surgeon to stay the knife and see what nature, aided by rational living, will do to arrest the progress of disease; Dr. Bulkley has this courage, and his courage is based upon experience. The book is well written, extremely interesting, and moreover provides food for a great deal of deep thought.

A MANUAL OF BACTERIOLOGY, CLINICAL AND APPLIED. By R. TANNER HEWLETT, M.D., F.R.C.P., D.P.H. (London), Professor of Bacteriology in the University of London; Director of the Bacteriological Department, King's College, London, etc. Fifth edition: 668 pages. Price, $4.50. St. Louis: C. V. Mosby Company.

THIS well known English manual of bacteriology has appeared lately in a thoroughly revised edition, the fifth. The author has added much new material from recent contributions to the general subject of bacteriology and protozoology, and the more important advances in immunity have likewise been included. The volume covers the basic principles of the subject quite thoroughly and at the same time gives prominence to their practical application. Incorporated in the chapters concerning the more important pathogenic organisms are sections with directions for the examination of materials for clinical diagnosis. Attention is given to the serological reactions, the technique of which is fully explained. Besides the addition of new material to the technical side of the subject, the question of the classification of microorganisms has been revised, and their characteristics are fully considered. The language is concise, and the subjects are presented without confusing particulars, yet still in sufficient detail for the purposes of the worker. The photomicrographs are well selected and clearly reproduced, adding much to the value of the book. Laboratory workers, as well as physicians and students, will find this manual most helpful.

ERGEBNISSE DER IMMUNITÄTSFORSCHUNG EXPERIMENTELLEN THERAPIE, BAKTERIOLOGIE UND HYGIENE (Fortsetzung des Jahresberichts über die Ergebnisse der Immunitätsforschung). Unter Mitwirkung hervorragender Fachleute, herausgegeben von Professor Dr. W. Weichardt, II Direktor der Kgl. bakteriologischen Untersuchungsanstalt in Erlangen. First Volume. Price, M. 22.60. Berlin: Verlag von Julius Springer, 1914.

OWING to the great increase in the amount of published material to be abstracted in the *Jahresberichte über die Ergebnisse der Immunitätsforschung*, it has been found impossible to continue publication in the same form. Certain of the Centralblätter now cover the ground very fully, and it has been considered advisable, therefore, to alter the form of the Jahresbericht, abandoning the abstracts and inserting only comprehensive review articles on certain phases of immunity. It thus becomes, as its title indicates, one of those extremely useful Ergebnissen which sum up from time to time a given subject. This first volume of the *Ergebnisse der Immunitätsforschung experimentellen Therapie, Bakteriologie und Hygiene* contains eleven papers, four of which are written by investigators in the United States and Canada. The most interesting are a paper by Eisenberg on mutations in bacteria, and a review by Rothacker of the biochemical methods used in identifying those digestive ferments which appear in the who are interested in the subject of immunity this new blood after injection of foreign substances. For those publication will prove a valuable work of reference.

THERAPEUTICS OF THE CIRCULATION. By Sir LAUDER BRUNTON, Bt.M.D., D.Sc., LL.D. (Edin.), LL.D. (Aberd.), F.R.C.P., F.R.S., Consulting Physician to St. Bartholomew's Hospital. Second Edition, with illustrations. Price $2.50 net. New York: Paul B. Hoeber, 1914.

THE first edition of the book consisted of eight lectures delivered by Sir Lauder Brunton in 1905 in the Physiological Laboratory of the University of London. The author has for long established a great reputation as an authority on therapeutics and on therapeutics of the circulation, and the first edition was recognized by the profession as an extremely useful contribution to the subject. Since the publication, however, of the first edition our knowledge of the circulation has been greatly amplified, particularly with regard to blood pressure, and in the present edition all the latest views have been recorded. A great part of the book is given up to physiology, pharmacology, and to the pathology of living structures, but, as the author explains, it is necessary to lay the foundations firmly before the superstructure, therapeutics, can be surely raised. The volume should prove a valuable supplement to the ordinary textbooks on the circulation.

CHILD TRAINING AS AN EXACT SCIENCE. A Treatise Based upon the Principles of Modern Psychology, Normal and Abnormal. By GEORGE W. JACOBY, M.D., Fellow of the New York Academy of Medicine, Member of the American Medical Association, American Neurological Association, and New York Neurological Society; Consulting Neurologist to the Hospital for Nervous Diseases, the German Hospital, the Beth Israel Hospital, the Red Cross Hospital, and the Infirmary for Women and Children in the City of New York. With illustrations. Price, $1.50. New York and London: Funk & Wagnalls Company, 1914.

THE aim of this work is to present a scientific exposition of child training as based upon the principles of modern psychology, medicine and hygiene. Following an introduction in which the author emphasizes the importance of appreciating the individuality of the child, the subject matter of this volume is dealt with under the four main headings: Historical Survey; the Psychic Abnormalities of Childhood; Prophylactic Training; and Therapeutic Training. In the section devoted to prophylactic training the author shows the importance of controlling inheritable disease in the parents and of legal enactments for preventing procreation by the unfit. As regards the training of the children he expresses admiration for the Montessori method, which, based uopn the original observations of Séguin and Itard, aims at the free, individual, self-development of the child. The Montessori method applies to normal children a mode of developing sensory activity that was originally designed by Séguin for the training of defective children only. Bodily development, including the use of the so-called "eurythmic movements," intellectual development, and the formation of character and the will are taken up in detail. The final section on therapeutic training includes chapters on the educable, causal treatment, symptomatic treatment, and the uneducable. In the final section the author tersely sums up the entire theme of his work: Child training must be based upon a knowledge of the experimental psychology of the child, the nucleus of which is the doctrine of psychophysical parallelism. Individualization is necessary in the training of the child and this can be accomplished only by the cooperation of the physician and the pedagogue. Dr. Jacoby has written in charming style a volume that cannot fail to be both interesting and valuable to the general reader as well as to the physician and educator.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 5, 1915.

DR. C. A. McWILLIAMS IN THE CHAIR.

Inguinal Hernia with Unusual Contents.—Dr. CHARLES E. FARR presented three cases which were of interest because of the contents of the sac. The first case was a child five years of age, who had a left inguinal hernia containing a loop of normal Fallopian tube. The ovary was at the internal ring. The second case was a right inguinal hernia in a girl eight years of age, which was partly unreducible. This sac contained the right Fallopian tube and ovary, very adherent and with the fimbriated extremity closed. This was freed and reduced with considerable difficulty. The third case presented was a male child three and a half months of age, who had a strangulated left inguinal hernia with a hydrocele. The contents of the hernia were cecum, appendix, and a loop of the ileum, and all were reduced with much difficulty. The appendix and cecum were apparently from the right side of the abdomen.

Compound Dislocation of the Right Elbow with Fracture of the Upper End of the Radius.—Dr. S. M. MILLICAN presented this patient. He was thirty-three years of age, an ironworker, who on September 17, 1914, dropped about twenty feet and received a long scalp wound and an injury of the right elbow. He was transferred to Dr. Millican's service that afternoon at the Lincoln Hospital, having had no treatment. The scalp wound was sutured and a posterior dislocation of the right elbow was reduced with some difficulty because the upper end of the radius had slipped away from the ulna. After reduction the arm was put up in posterior moulded splints and flexed as far as the swelling allowed. *X*-rays on the following day showed a fragment from the anterior surface of the upper end of the radius displaced so that it lay between the bones of the arm and forearm, preventing full flexion. Under ether the fragment, about the size of the tip of the little finger, was displaced outward so as to lie external to the joint area. The arm could then be put up in extreme flexion and was so maintained for a little over two weeks. The patient was then allowed to have only a sling and encouraged to move the elbow and forearm as much as he would. There were originally lacerated wounds over the inner aspect of the elbow which communicated with the ulna. All the wounds healed properly and the patient was discharged at the end of three and a half weeks, with the arm supported in a sling. Dr. Millican had kept track of him since then and his notes were as follows: The accident occurred on September 17, 1914. On October 16 there was complete flexion, but extension was 10 degrees less than a right angle. There was no motion between the bones of the forearm, and the patient was encouraged to extend the arm. Four days later he could get the arm about 5 degrees below a right angle. On October 30 he could extend the arm about 15 degrees below a right angle and there was a considerable range of pronation and supination in the hand due to the movements in the carpus. He could get no motion between the forearm bones. On December 1 he had extension to about 10 degrees less than a straight line, and full range of flexion; there was very slight motion between the forearm bones. About the middle of December the patient went back to work, where he could use a hack-saw, and was encouraged to do everything he could; the tone in the forearm muscles and arm immediately returned and the range of motion in the forearm bones was now about 5 or 6 degrees. On January 15 he could use his arm quite freely except that he was afraid to depend on it for emergencies which kept him working on the ground. The extension was still limited about 10 degrees and the forearm had much improved; there was now about 10 degrees range of motion, pronation, and supination, and he felt that the arm was much stronger and was quite useful, although still the motion was too limited. The *x*-ray made about the middle of December showed the fragments displaced to the outer side and attached to the lower part of the neck of the radius well away from the joint surfaces. It seemed as if adhesions between the orbicular ligament and the fractured surface of the upper end of the radius were now the limiting causes. The displaced fragment rotated with the shaft of the radius and seemed to check the range. Inasmuch as improvement had been so rapid since he began to work he was inclined to let well enough alone and see if further motion would return. Dr. Millican said he would be very glad to have an expression of opinion as to the advisability of doing an operation if no further improvement took place.

Two Cases of Blood Transfusion by a Greatly Simplified Method.—Dr. RICHARD LEWISOHN presented several patients upon whom he had applied the method of citrated blood transfusion (see MEDICAL RECORD, January 23, 1915). He discussed the experimental part of his work, which proved that sodium citrate added to the blood at the ratio of 0.2 per cent. kept the blood from clotting during the transfer from the donor to the recipient. This small amount of sodium citrate was absolutely harmless. Dr. Lewisohn said that he had applied this method in ten cases (the largest amount transfused being 900 c.c. of blood) without any ill effects on the patient. Clinically the citrated blood seemed to be just as effective as normal blood. The hemoglobin was increased in the same proportion as by ordinary transfusion and rose automatically during the week following the transfusion. This was, in his opinion, the best proof of the good quality of the transfusion. The technique was extremely simple, as simple as an ordinary saline infusion.

Dr. LINDEMAN said that unless sodium citrate was used the method demonstrated by Dr. Lewisohn was not desirable. He had gone deeply into the problem and found that with that method he could not embody just what he had in the cannula system. The blood should be transfused in a condition as close to nature as possible. Some years ago this plan of Dr. Lewisohn had been suggested to him and he had used a 1 per cent. solution of sodium citrate. Dr. Lewisohn's method might be applicable to one, two, or three cases, but a truly practical method should be applicable to every case. By his method he had recently given 1,100 c.c. in six and one-half minutes without the slightest danger.

Dr. FENTON B. TURCK said that inasmuch as some of the remarks referred to experiments that had been made, he wished to ask some questions in reference to these experiments. For a number of years he had experimented on a great number of animals, relating to the blood and blood serum, and it seemed to him that more experimental work was required to support the clinical application. In the intestines the reaction in the blood occurred within two hours after the injection of cultures into the intestines. It was found that as the microorganisms passed through the mucosa into the submucosa and came in contact with the tissue fluid, there was a reduction of the anti-ferment of the blood by absorption. Now, if the injection of blood increased or replaced the anti-ferment, which could be determined by appropriate methods, would the addition of sodium citrate interfere with this reaction? By the injection of sodium citrate alone, would the anti-ferment replacement be interfered with? Chloroform, alcohol, and many salts did interfere with it. Dr. Turck said he wished also to ask regarding the effects of the injection of the serum itself upon the blood, not only the human serum, but that of other animals, and especially young animals. These were points about which, as clinicians, they should know something.

Dr. JOSEPH WIENER believed that the method described by Dr. Lewisohn would bring about a new era in blood transfusion. He had seen one or two cases in which the results of the transfusion were as satisfactory as could be desired. He had done many transfusions and he knew that Dr. Lindeman's results were very brilliant in his own hands, but Dr. Wiener said he could not get the same results, nor could other surgeons. What had just been presented was a very simple method and very efficacious; the procedure was effected in the same way as the injections of neosalvarsan, and could be done in ten minutes. There was another adjunct to this method—they could store blood for one or two weeks and then use it. The method of blood transfusion as now employed was rather cumbersome; the method just presented would do away with objection. The main point was to get something that was simple, safe, and efficient in blood transfusion. He believed that in one year everybody would use this method. The blood could be kept two weeks in the ice-box after adding sodium citrate and could then be used with good results.

Dr. LEWISOHN, closing the discussion, said that Dr. Lindeman's method was a splendid one in the latter's hands. The technique, however, was too complicated and, therefore, the results in the hands of others had not been entirely satisfactory. Dr. Lewisohn gave

some further details in reference to his experimental work in answer to Dr. Turck's remarks. The citrate method seemed to combine great simplicity in its execution with perfect safety for the patient. He hoped that its application on a larger scale would give the same results to others as it had given him in this series of ten cases.

Derangements of the Inferior Radio-ulnar Articulation.—Drs. William Darrach and Kirby Dwight presented this paper, which was read by Dr. Dwight. He stated that dislocations of the ulnar head without fracture of the radius were quite uncommon, there being only about 33 cases on record. Such dislocations occurred as a result of extreme forcible supination, or, less commonly, pronation. The ulnar head usually slipped forward, rarely backward. There was an increase in the antcroposterior diameter of this region and a decrease in the lateral. The ulnar head could be felt either in front or behind, and the empty sigmoid cavity of the radius was palpable. When in front the pressure on the ulnar or median nerves and flexor tendons might give intense pain and interference with flexion of the fingers. When seen early and the diagnosis made, reduction was usually easy. With proper support a complete cure would result. If the wrist was used too soon the supporting structures might become lax enough to allow a subluxation on extreme supination alone, or on flexion in the supine position with counterpressure on the hand. To guard against this a leather wristlet should be worn for several months. If the condition had not been recognized and the ulnar head had remained out of position for some weeks, reduction might be difficult or impossible without open operation; in such cases a subperiosteal resection of the ulnar head would give a marked improvement in the usefulness of the part. Dislocation associated with fracture of the radius was of quite frequent occurrence. With a proper reduction of the fracture the ulnar head would resume its normal position. The condition was frequently overlooked. The possible association of this injury should always be borne in mind in any fracture of the lower portion of the radius. The interference with flexion of the fingers might be the most marked symptom, or the nerve pressure might be the predominant sign. When recognized early, reduction was usually easy and the treatment was the same as when the dislocation occurred alone. Sprains of this joint could occur without actual dislocation and without fracture of the radius. The capsule or the attachment of the meniscus might be so stretched or torn as to give rise to laxity of these structures and later on allow a partial subluxation on certain movements. Proper protection after the original injury would prevent this, and the use of a tight leather wristlet later would lessen the disability in neglected cases. Derangement of the inferior ulnar joint resulting from fracture of the radius with displacement might be manifested by radial and dorsal shifting, dorsal tilting, and impaction, and these usually occurred in combination. As was stated, in a simple transverse fracture of the lower extremity of the radius the distal fragment might be displaced in eleven distinct ways, singly or in combination. In most of these positions, but especially with radial shifting and impaction, there was a change in the relationship between the ulnar head and the sigmoid cavity of the radius. The ulna tended to maintain its relationship with the upper fragment, and there was frequently a stretching or tearing of the capsular ligament of the inferior radioulnar joint. With a perfect reduction the normal relationship was regained and the injury was repaired during the repair of the fracture. The displacements of the lower fragment, however, were frequently not completely overcome and the normal relationship of the ulnar head was not obtained. This was especially true if there was much impaction, when the relative lowering of the ulnar head could be made out. A large proportion of the ulnar head pain, limitation of pronation, supination, and adduction following Colles' fracture was due to derangement of the inferior radioulnar joint. The same result was obtained in radial fractures at a higher level if any shortening of the radius occurred. The relative lowering of the ulnar head deranged the articulation. In the majority of the cases the proper reduction of the displacement would restore the normal relations of the joint sufficiently to avoid any long persistence of these symptoms. The ligaments, however, would need support after the fracture had completely healed. This fact explained the comfort found in simple strapping of the wrist or the use of a leather wristlet after the removal of the splints. In cases with much radial shifting or impaction the deformity of the prominent ulnar head might be sufficient to cause considerable annoyance to the patient. The three symptoms, pain, limitation of rotation, or deformity, if at all pronounced and if they persisted much beyond the normal period of convalescence, were indications for operative interference. Very marked improvement could be obtained by a superiosteal removal of the lower inch of the ulna, leaving the styloid process in place. Emphasis was laid on the latter point and on not removing the periosteum in order to preserve the attachment and support of the internal lateral ligament. If the periosteum was left intact there would be a more or less complete regeneration of the ulna, the shape of the bone adapting itself to the functional demands, and the strength of the wrist would return to almost normal. An incision was made on the ulnar aspect of the bone extending from the styloid process upward for an inch and a half. This was deepened through the periosteum which was reflected from the bone with a sharp elevator. The ulna was cut through with a Giglin saw or rongeur, and the distal fragment tilted out. The attachment of the capsular ligament was cut out and the head turned out. The bone was then cut across obliquely, leaving in the styloid with a small portion of its base, so as not to interfere with the attachment of the meniscus. The periosteum was then closed with plain catgut and the skin sutured. A starch bandage from the midforearm to the metacarpal heads was sufficient and could be removed in a week or ten days. The patient was urged to begin pronation and supination at the end of a week and could usually return to light work at the end of ten to fourteen days.

Treatment of Fracture of the Elbow by Immobilization in Hyperflexion Combined with Early Passive Movements and Massage.—Drs. Harold Neuhof and Heinrich Franz Wolf presented this communication. They stated that an unusual opportunity had been given them for the study and treatment of a large number of elbow fractures referred from Mount Sinai Hospital and the eight surgical departments of its dispensary. They termed all results "imperfect" which were not absolutely perfect. After reviewing the literature and showing the percentage of perfect results obtained by others, and referring to the work of Ashhurst who reported a series of 56 cases treated by the so-called Jones position for elbow fractures in which the end results were perfect in 81 per cent. of the cases, they stated that they hoped to prove the advantages of this posture over others in the treatment of elbow fractures. They believed that the reason that Ashhurst did not obtain an even higher percentage of perfect results was because of the relatively prolonged immobilization which he practised and the absence of passive movements and massage from the after treatment. Their paper was written in part to verify this assertion. Their group of 100 cases had been seen from 1911 to 1914. No selection of material had been made; the cases included simple and comminuted fractures, supracondylar fractures, those of the humerus that entered the joint, those of the upper end of the radius and ulna, and in fact all types of fracture, at the elbow joint. Recently observed cases were not included. These fractures occurred most frequently in children in the tenth year. A notable increase in the incidence of these fractures was observed in the fifth year and steadily increased up to the tenth year when it again began to decrease. For the purposes of the paper the following classification had been adopted: (1) Supracondylar (including diacondylar); (2) External condylar (including capitellum and epicondyle); (3) Internal condylar (including trochlear and epitrochlear); (4) Upper end of ulna; (5) Upper end of radius. The interval after fracture at which the patients were referred varied considerably; some of the departments sent all their elbow fractures while others sent only those which did not seem to be doing well under ordinaray methods of treatment. This must be considered in the interpretation of statistics. The final discharge with a perfect result was made in 53 per cent. of the cases; the remaining 47 per cent. presented results more or less imperfect. The tabulated results in the different groups above mentioned demonstrated that the chances for cure did not depend, to any great extent, upon the type of fracture. Studying the relation of perfect results to the period of immobilization of the elbow, they found that the outlook for perfect results was by far the most favorable when the fractures were

immobilized for the briefest period possible, and when massage and mobilization were instituted thereafter. A comparison of the average number of days of immobilization for the group of perfect results with that of the imperfect ones, showed that the difference was equally striking in all the varieties of fracture. Patients finally discharged with a perfect result were referred for mobilization and massage at periods averaging 12.8 days after fracture. Patients finally discharged with an imperfect result were referred for mobilization and massage at periods averaging 32.1 days after fracture. It was also found that fractures yielding a perfect result generally required a much shorter period of massage and mobilization than those yielding an imperfect result. In 23 cases in which fixation in hyperflexion (by Dr. Neuhof) was combined with early mobilization and massage the results were perfect in all but one case. In this case the fragments could not be set in good position and operation was refused. A perfect result was not obtained in any of the cases operated upon and subsequently sent for mobilization and massage. They could not say whether the results would have been different had these patients not been operated upon. In describing the rationale and the technique of hyperflexion the authors stated that from the viewpoint of leverage the position of hyperflexion for fracture of the elbow was more advantageous than that of flexion at any angle less than the most acute obtainable or in the position of extension. Any flexion short of hyperflexion did not abolish the lever action of the forearm. Hyperflexion was as correct for the maintenance of the carrying angle as it was for leverage. Most of the unfortunate results of fracture of the elbow consisted in limitation of flexion. There was no way of determining in advance what the result of any elbow fracture would be. Limitation of motion in a well flexed elbow was the least disadvantageous form of limitation. From this viewpoint hyperflexion was also the most desirable position. Their experience showed that the results of fractures of the condyles and of the upper end of the radius were as good as those of supracondylar fractures when fixation in hyperflexion was combined with massage and mobilization. Before the elbow was placed in hyperflexion all displaced fragments should be reduced and the results of attempts at reduction should invariably be controlled by radiograms taken immediately after, so that any pronounced displacement remaining could be corrected. They ascribed a share of the results in their cases treated by hyperflexion to a minimal amount of trauma inflicted in the examination and fixation of the injured elbow. The point should be emphasized that hyperflexion did not mean merely acute flexion, but the most acute flexion in which the elbow could be fixed without obliterating the radial pulse; this generally varied between 20 and 35 degrees. In discussing the rationale and technique of mobilization and massage, the authors said that any fear of displacement of the fragments and of formation of excessive callus had proven unfounded in their hands. The most important rule for early massage and mobilization was that the treatment must be practically painless. This rule had proved the best way of avoiding accidents. The treatments, generally of fifteen to twenty-five minutes duration, consisted in the beginning of gentle stroking massage of the arm and slight flexion and extension movements at the elbow. At later periods the treatment was more and more vigorously practised. All sudden movements of the arm were very carefully avoided. The elbow was always supported during treatment and was fixed in hyperflexion after each treatment. The treatment was given daily in the great majority of cases. Although massage might be instituted immediately after the injury an absolute rule for the time to begin mobilization could not be given. The *x*-ray picture and the freedom from pain in the first trials were the best guides. Mobilization might be tentatively essayed as soon as the fourth or fifth day after the fracture. The earliest attempts should be made when the *x*-ray picture showed simple or impacted fractures, or small fragments of bone so situated that their healing in place might prove a mechanical hindrance. Active and passive motions at the shoulder and in the hand were instituted from the outset. Active motions were never necessary during the period of mobilization and massage. The length of time that the elbow was in the hyperflexion bandage depended upon the union of the fracture and the type of patient.

Supracondyloid Fracture of the Humerus.—Dr. WILLIAM C. LUSK said that he would like to speak of supracondyloid fracture of the humerus of the extension type. In his opinion the perfect result following this particular fracture depended upon the getting of a complete reduction of the fractured fragments. If the upper fragment projected a little forward callus would be thrown out by it, which would interfere with flexion. This brought up the question of how to reduce this fracture, which was not always easy to do especially when the fracture was of the transverse type. He had written an article (*Annals of Surgery* XLVIII, 1908, p. 432) previously, describing a method of reducing this fracture. The secret of effecting the reduction of this fracture lay in a knowledge of the fact that, anyway in some cases, the posterior periosteum was not torn across but simply became stripped off from the lower two or three inches of the posterior surface of the upper fragment, thus forming a bridge of unyielding tissue between the fragments whose restraining influence on reduction of the fragments must be reckoned on. Thus in the position of deformity, the upper fragment overriding the lower anteriorly, it can be seen that flexion of the forearm will make this periosteal bridge taut and lock the bones more firmly together in their malposition. But on the other hand by hyperextension of the forearm the posterior periosteal bridge will be relaxed and at the same time the planes of the fractured surfaces will be thrown apart at an angle, the apex of which is at their posterior margins, which position is the one in which reduction is possible. Thus with the forearm hyperextended, thereby relaxing the periosteal bridge and causing the unlocking of the bones, by making downward traction on the forearm and at the same time pushing the lower fragment forward, the posterior margins of the fractured surfaces are first brought into alignment, after which, holding firmly the ground already gained by forward pressure on the olecranon and backward on the arm, the forearm is brought into acute flexion which closes together the angle between the planes of the fractured surfaces produced by the hyperextended position. If it were impossible to completely reduce a supracondyloid fracture of the humerus early on account of great swelling around the elbow, proliferation in the meantime from the separated periosteum might be an obstacle to effecting later a complete reduction, by mechanically interfering with full forward replacement of the lower fragment. When reduced, the next question was how to hold this fracture in perfect reduction. Where the position of acute flexion alone with no especial support for the fragments had been employed to maintain the reduction, even though plaster of Paris fixation were used, there had seemed always to be a tendency for the lower fragment to luxate a little posteriorly. In the last two cases of this fracture he had treated, Dr. Lusk said he had maintained a perfect reduction by the employment of a folded gauze pad held in place by adhesive plaster over the lower fragment, against which forward pressure was made during the application of the plaster of Paris bandage, the pressure being maintained until the plaster had hardened. Of one case in the service of Dr. Joseph B. Bissell at Bellevue Hospital, he showed an *x*-ray picture demonstrating a perfect reduction with the forearm in acute flexion and the posterior pad in position supporting the lower fragment. A previous attempt to maintain the reduction of this fracture in plaster of Paris with the forearm in acute flexion without the use of the pad support, had left still a little forward overriding of the upper fragment. The second case was a child in which the *x*-ray showed a perfect reduction, and there was recovery of complete flexion and extension. It took three people to reduce and immobilize this fracture, not including an anesthetist—one to manipulate the forearm and lower fragment, one to press continuously backward on the shaft of the humerus, and the third to apply the plaster. No turn of the bandage should be made across the flexure of the elbow.

Dr. NEUHOF closed the discussion. He agreed with the statement that it was particularly desirable to operate when there was an upward displacement of the fractured head of the radius and when this fragment interfered with flexion of the elbow. Displacement was not, in itself, an indication for operation, as shown by a case in point described by Dr. Neuhof. In regard to the question about end results in these cases of elbow fractures, it was difficult to make any definite statement. Some patients appeared to have reached their maximum improvement in six months; in others, however, improvement went on, he believed, for one year. The best results were obtained where reduction was not postponed but effected when the patient first came under observation.

SECTION ON MEDICINE.

Stated Meeting, Held March 16, 1915.

DR. T. STUART HART IN THE CHAIR.

THE contributions to the program of the evening were from the Medical Service of the New York Hospital.

The Work Limit with Auricular Fibrillation.—Dr. HAROLD E. B. PARDEE presented this communication, in which he stated that, while they had a very fair idea of the amount of restricted activity imposed by the different lesions of the cardiac valves, they were only lately coming to realize that an irregular heart did not of necessity seriously cripple the individual. Sinus arrhythmia they knew might be disregarded and usually looked upon as normal, nor did extrasystoles seem to lead to hypertrophy or cardiac failure even when present constantly over long periods of time. Opposed to these, the continuous irregularity of auricular fibrillation had been looked upon as a grave abnormality of function; it was his endeavor to point out how this view might be modified. If the heart rate exceeded 70 or 80 beats per minute for any considerable period of time, the effect on the circulation was such that symptoms of cardiac failure would arise. The heart needed a diastole of certain duration in order that the ventricle might have time to recover its contractile power, and to fill sufficiently with blood from the auricle. Diastole was shortened much more than systole as the rate of the heart increased, so that the heart suffered from insufficient rest and insufficient filling, and the blood pressure fell or the arteries harrowed in an attempt to keep it up. When auricular fibrillation was present the ventricles usually responded with an irregular rate of about 90 per minute. This might not be accompanied by symptoms on the part of the patient, but on attempting moderate exertion, dyspnea, palpitation, or precordial discomfort appeared, though they might not persist long afterwards. Without treatment the course was one of progressively increasing limitation of activity; the symptoms appeared with less provocation, the heart rate was rapid in the intervals, edema appeared, and the patient was confined to his room or to his chair. This breaking down of the cardiac reserve took a variable amount of time, but in the author's opinion it varied from two or three to many months, though it was usually impossible to mark exactly the time of onset of the fibrillation. Under energetic treatment this cardiac failure was promptly corrected. The tincture of digitalis is m.xx doses four or five times daily, or an equivalent amount of the other preparations would usually relieve the dyspnea and palpitation in twenty-four to forty-eight hours, and by the fourth day the patient was quite comfortable and the heart rate reduced to 85 or 90. By reducing the dosage of digitalis properly its toxic effects could be avoided and the heart rate kept in the neighborhood of 60 to 80 per mintue. The patient was now, from the physiological standpoint, just where he was at the onset of the fibrillation, except that the heart would be affected more readily when called upon for extra effort. If treatment was discontinued in a month or two or more, the cardiac insufficiency would be reestablished and the patient again confined to his chair. The patient must not be discharged when he had recovered his strength after dilatation but must be kept under observation, must continue the digitalis, taking enough of the drug so that its effect on the vagus would maintain the rate of the heart at its optimum, usually about 70 per minute. The amount of digitalis required to do this varied from m.x to m.xl of the tincture daily in divided doses. The author cited a number of cases which illustrated what could be done toward making the patients comfortable and even useful, enabling them to continue at their work over a considerable period of months or years, as long as they faithfully took the digitalis in sufficient amount. The results in these cases seemed to form a basis for the conclusion that this disease need not be the reason for a bad prognosis and that it was not incompatible with an average degree of bodily exertion at least, and at times somwhat more. The most important factor was not the irregularity, but the quality of the cardiac muscle, and the presence or absence of valvular lesions, or of increased arterial tension.

DR. LEWIS A. CONNER thought Dr. Pardee had brought out a very important point in emphasizing the need for continuous digitalis medication in patients with auricular fibrillation who had recovered from their decompensation and were attempting to resume their ordinary mode of life. He believed that the common error was to use digitalis so intermittently and in such small doses that no real effects were obtained.

DR. PARDEE said that it seemed to him more reasonable that patients should have determined for them the amount of digitalis necessary to produce the effect and should take that amount regularly. He admitted, in spite of this, that the patient might be in good condition physically and yet not feel so well with m.xxx daily as with m.xl.

Intravenous Use of Sodium Salicylate in Rheumatic Fever.—Dr. LEWIS A. CONNER said that this method had been employed in his service at the New York Hospital during the past year and a half and that during this time some 50 cases had been so treated and about 400 intravenous injections given. Mendel, in 1904, was the first to call attention to the feasibility of this method of administration. Even though relatively small doses were used he was struck with the marked analgesic effects produced and thought the method possessed many advantages over the usual form of administration by mouth. His conclusions were supported by Behr, Rubens, and Winkelmann, but were questioned by Brugsch and by Doevenspeck, who could see no advantages of this method over the usual one and who found the injections frequently painful and liable to local complications. Since then the method seemed to have attracted very little attention. When Dr. Conner began to use this method he found that the dose used by Mendel, six or eight grains twice a day, produced very little effect, but when considerably larger doses were used that prompt and marked effects could be obtained. To his solution of sodium salicylate Mendel added a certain amount of the sodio-salicylate of caffeine but in the larger doses employed Dr. Conner found the caffeine objectionable and thereafter the sodium salicylate was used alone. In order to render the injections free from unpleasant local and constitutional effects it was necessary to observe carefully certain precautions. First, the solution should be made only with the chemically pure, crystalline form of sodium salicylate and not with the ordinary amorphous form of the drug in common use, and a fresh solution should be made every three or four days, as the solutions tended to deteriorate on standing. Second, a fine needle should be used in order that the trauma to the vein wall might be as slight as possible, and that the injection should be made slowly; and, Third, care should be taken to use a large vein and to see that none of the solution escaped into the neighboring subcutaneous tissue. The method used was as follows: A stock solution was made by dissolving 10 grams of crystalline sodium salicylate in 50 c.c. of freshly distilled and sterilized water. The drug was weighed and handled as aseptically as possible and no further sterilization was done after the solution had been made. From 5 to 10 c.c. of this solution (15 to 30 grains of the drug) was injected into an arm vein, usually at intervals of 8 hours; an all glass syringe and a needle slightly larger than the ordinary hypodermic needle being used. The injections were usually made alternately into each arm, the same vein often being used several times. Usually the injections were entirely free from pain and from any unpleasant local or constitutional reaction, even when doses of 30 grains were given. In four instances there resulted some inflammation of the vein, with thrombosis, near the point of the puncture, which gradually subsided without any unpleasant consequences. At first injections of the larger doses were occasionally followed by a chill or by some nausea, but since the crystalline form of the drug had been used these reactions had ceased. In one patient each injection had been followed by sharp pain and cramp in the muscles of the shoulder and arm which seemed to be due to some individual sensitiveness as the same stock solution and dosage in other patients produced no such effect. With regard to the value of the intravenous method Dr. Conner believed that it would never replace the usual method of mouth administration in routine cases, but thought that it was of great value in patients who could not tolerate the drug in sufficient amounts by mouth, and in those in which a marked and prompt effect was urgently required, as, for example, in severe cases with high temperature and intense pain, or those in which heart complications seemed to threaten. He had found the relief of pain much more pronounced and prompt when the drug was given intravenously. The effect on the temperature and on the local inflammation was less striking, but he believed his cases showed conclusively that

the duration of the fever and of the disease was shortened when intravenous injections were used during the acute stage. At present in his wards the routine treatment of all severe cases of rheumatic fever was to administer full doses of sodium salicylate by mouth and, in addition, for the first two or three days to give three daily intravenous injections of the drug; 30 grains were given at each injection if the patient was a full-sized and vigorous adult.

General Suppurative Pneumococcus Peritonitis.—Dr. WILLIAM R. WILLIAMS reported this case, which occurred in a child three years of age. The patient was admitted to the New York Hospital on October 25, 1914, complaining of loss of appetite and fever. The family history was negative. The child had had measles eighteen months before and scarlet fever one year ago. For two weeks the patient had been complaining of loss of appetite, fever, and constipation, but had no cough, chills, or sweats. Physical examination revealed a discharge from the left ear. The lungs showed a few scattered crepitant râles. The white blood cells numbered 11,600, with 85 per cent. polymorphonuclears. The liver extended 4 cm. below the costal margin. Four days later the left ear-drum perforated and S. viridans was recovered from the discharge. There was dullness from the spine to the base of the scapula on the left side, high-pitched, harsh breathing, and a few sonorous and sibilant râles. On the fourteenth day it was noticed that the abdomen was increasing in size, and three days later a definite fluid wave was detected. Two hundred and fifty c.c. of greenish-yellow pus was aspirated. The child was transferred to the surgical ward, and at operation 750 c.c. of pus was evacuated. There was no sacculation. It was thought that they were dealing with a tuberculous peritonitis and the abdomen was closed. Ten days later the wound broke down and 1,000 c.c. of pus was discharged. The wound then healed up and the child was discharged as cured on January 15, 1915. The microscopical examination proved that they were dealing with a pneumococcus infection.

Diagnosis of Intrathoracic Neoplasms by Exploratory Puncture.—Dr. HUGHES DAYTON reported this case because it demonstrated the diagnostic value of evamination of the tiny fragments of tissue obtained by exploratory puncture with an aspirating needle of moderate size in cases of intrathoracic lesions of doubtful character. The patient was a musician, nineteen years of age, who entered the New York Hospital complaining of cough and pain in the right side. His family history was negative and he had had no previous illness excepting gonorrhea nine months before admission, which was followed by double inguinal adenitis six months later. Soon after this he began to have pain in the right side, increased by deep breathing or coughing. There was dullness over the right chest posteriorly from the spine of the scapula to the base, increasing to flatness, diminished fremitus, breath, and voice sounds, and voice and whisper of nasal quality with a few subcrepitant râles. Aspiration of the right chest yielded a syringeful of bloody fluid containing many small opaque particles, which consisted of cells resembling epithelium. Fluoroscopic examination on the following day showed a shadow extending from the spine of the right scapula to the diaphragm. Within this area were two semitransparent areas. A radiogram was reported as showing pleurisy with effusion. There was a daily afternoon rise of temperature of 1 to 2 degrees. The pulse ranged from 72 to 112, averaging about 88. The blood examination showed 6,140,000 red blood cells, with 90 per cent. hemoglobin; 10,500 leucocytes on several occasions, but ranging from 7,500 to 18,000; polymorphonuclears, 54 to 85 per cent.; mononuclears ranged between 16 and 26 per cent.; basophiles, from none to 2 per cent.; eosinophiles, from 1 to 16 per cent., remained about 7 per cent. The Wassermann reaction was negative. Other examinations were negative. On April 9 a loud friction rub was heard over the entire right chest anteriorly, and the nasal quality of voice was confined to a small triangular area at the base of the right axilla. On April 14 the patient began to complain of pain in the right lumbar region, which varied in intensity during the remainder of his two weeks' stay in the hospital. The convex upper level of the shadow in the chest, with its semitransparent areas, the blood-tinged chest fluid, the displacement of the heart toward the left, the presence of a typmapitic area between the area of cardiac dullness and that of dullness in the right chest anteriorly, with a friction rub over the area of dullness, the persistent eosinophilia in the absence of intestinal parasites or other obvious cause, and the irregularity of the areas of nasal voice, all suggested the existence of a neoplasm rather than of a serofibrinous pleurisy. To substantiate this opinion a needle was inserted into the right chest in the ninth space near the angle of the scapula in order to obtain a fragment of tissue for examination. The needle encountered resistance from the start, which became greater within the chest. Three c.c. of blood-tinged serous fluid was withdrawn, which showed chiefly lymphocytes with a few eosinophiles, polymorphonuclears, and basophiles. The fragments of tissue obtained measured about 1 mm. by 1.5 mm. Dr. William C. Clark, who examined them, made a diagnosis of angiosarcoma. An April 29 the patient left the New York Hospital and on May 3 was admitted to the German Hospital. Here a tumor was removed from the right chest and death occurred on the same day. The pathologist's report confirmed the diagnosis made from the fragments obtained by puncture. Encouraged by this success the speaker had attempted the same unsuccessfully in two other cases: in one because the tumor was confined to the root of the lung, where puncture would have been dangerous, the rest of the lung showing pneumonia consolidation; in the other case the fragments removed by puncture consisted of fibrinous exudate containing lymphocytes with a single group of large, unevenly staining cells which resembled endothelium; the removal of a subclavian lymph-node showed infiltration of the surrounding tissue with cells resembling those of so-called endothelium of the pleura. The writer concluded that examination of fragments of tissue obtained by exploratory puncture was of diagnostic value only when the results were positive; but in these instances it might be of real value in differentiating from syphilis and tuberculosis.

Lantern Slides of Pneumonic Consolidation.—Dr. JOSEPH C. ROPER showed a series of lantern slides of pneumonic consolidation in children. The ease with which the child could be transported, the slight disturbance, and the short exposure necessary made the *x*-ray observations of the pneumonic process in children very easy. While all the plates showed the pneumonic process, even when the signs were not very distinct, they also showed a times abnormalities which could not be readily explained by the physical signs or the course of the disease. Further study, aided by postmortem examinations, would be necessary. The plates proved useful in diagnosing early pneumonic process in cases in which the pain was referred to the abdomen and in which the physical signs were indefinite. Of considerable interest was the persistence of a distinct shadow long after the temperature had become normal and when the physical signs remaining consisted only of slight relative dullness. In cases in which the temperature was prolonged the plates readily excluded empyema.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF NEW JERSEY.

October, 1914.

ANATOMY.

1. Describe the structure of the arteries and give their nerve and blood supply.
2. What arteries, muscles, and nerves would be severed in a cross-section at the middle of the humerus?
3. What are the lymphatic glands?
4. Give the situation of the lymphatic glands of the chest.
5. Locate and describe Peyer's glands.
6. Give the deep and superficial origin, course, and distribution of the pneumogastric nerve.
7. Bound Scarpa's triangle and mention the vessels and nerve in it.
8. What bones enter into the formation of the nasal fossæ?
9. Name the bones that form the ankle-joint and give their relations.
10. Name the abdominal viscera wholly covered with peritoneum; those partially covered.

PHYSIOLOGY.

1. Define physiology.
2. Trace the circulation of the blood beginning at the left ventricle.
3. How does the fetal circulation differ from that of the adult?

4. Give the physical and chemical composition of blood.
5. What are the functions of blood?
6. What is the portal system? Name the enzymes manufactured from its blood.
7. Name the organs of excretion in order of importance.
8. What is the function of the red blood cells? Of the leucocytes?
9. What is glycogen? What is its use?
10. What changes occur in a muscle in exercise?

CHEMISTRY.

1. What is chemistry?
2. What are the three laws of chemical combination?
3. Name three strong mineral acids and which is the strongest?
4. What are alkaloids, and how are they divided?
5. What is the chemical composition of the blood?
6. Give the antidote for poisoning by carbolic acid.
7. What are physical and what are chemical changes?
8. Define organic and inorganic chemistry.
9. Define specific gravity. What relation does the amount of solid matter in urine bear to the specific gravity of the urine?
10. What is the formula of hydrogen dioxide and by what other name is it known?

MATERIA MEDICA AND THERAPEUTICS.

1. Name three drugs that will liquefy and increase bronchial secretion. Give official name, dose of each. Write a prescription containing one.
2. Define a diuretic; name three vegetable diuretics. Give dose and official name of each. Write a prescription containing one.
3. Name two drugs that will lower blood pressure. Give official name and dose of each.
4. Name two official drugs that will change the color of the urine; also name two that will change the color of the feces.
5. What is epinephrin? Give official name, dose, properties, and uses.
6. Name three drugs that may cause irritation or skin eruption. Give official name, dose, and properties of each.
7. Oil of santal; give dose, properties, and uses; official name.
8. Elaterin; give official name, dose, properties, and uses.
9. What drugs would you use in the early stages of a case of pneumonia? Give official name; dose of each. Write a prescription containing one.
10. Name five official tinctures and give dosage of each.

HISTOLOGY.

1. Describe the suprarenal capsule, macroscopically and microscopically.
2. What do you mean by the reconstruction of anatomical structure? Give technique.
3. Describe epithelial tissue; give varieties and where found.
4. Describe motor nerve endings in voluntary muscle tissue.

ANSWERS.

ANATOMY.

1. An *artery* consists of three coats: The tunica interna, or internal coat; the tunica media, or middle coat, and the tunica adventitia, or external coat. The internal coat consists of a basement membrane, on which is a layer of endothelial cells. The middle coat consists of involuntary muscle fibers, between the layers of which are some elastic fibers. The external coat consists of connective tissue (white fibrous and yellow elastic). Between the two outer coats is an elastic membrane.

The *nerve supply* is by the vasomotor nerves. The *blood supply* is by the vasa vasorum.

2. Brachial, superior profunda and inferior profunda *arteries;* biceps, triceps, and brachialis anticus *muscles*; median, ulnar, internal cutaneous, musculospiral, and musculocutaneous *nerves.*

3. *Lymphatic glands* are solid bodies, of variable size, situated in the course of the lymphatic and lacteal vessels; they are surrounded by a capsule, and are filters through which lymph and chyle flow.

4. *Lymphatics of the thorax.* The *intercostal* lymphatic vessels, derived from the side of the abdomen and thorax, pleuræ, diaphragm, spinal canal, muscles of the back, etc., follow the course of the veins, traverse fifteen to twenty intercostal glands near the heads of the ribs, and terminate in the thoracic duct. The *posterior mediastinal glands* are between the intercostal glands, and communicate with them. They receive vessels from the pericardium, esophagus, and diaphragm. Some of the efferent vessels end in the bronchial glands, others in the thoracic duct. The *anterior mediastinal lymphatic vessels* are derived from the anterior wall of the abdomen and thorax, the diaphragm, pericardium, upper surface of the liver, heart, and thymus gland. They traverse about eighteen to twenty *anterior mediastinal glands*, situated in the course of the internal mammary vein, pericardium, and great vessels of the heart, and terminate in thoracic and right lymphatic ducts. The pulmonary lymphatic vessels consist of a superficial and deep set, traversing in the last part of their course the pulmonary glands. The *bronchial glands* are twenty or more glands at the bifurcation of the trachea and root of the lungs, and receive the lymphatic vessels of the lungs and bronchi. They become pigmented, and are often the seat of disease. Their efferent vessels terminate on the right side in the right lymphatic duct, either directly or by forming the broncho-mediastinal trunk, and on the left side in the thoracic duct. —(Young's *Anatomy.*)

5. *Peyer's glands* are large, oval groups of lymph follicles; practically they are groups of solitary follicles; they are from half an inch to four inches in length, and are situated throughout the small intestine but are largest and most numerous in the ileum.

6. *Pneumogastric nerve. Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Course:* Outward across the flocculus, to jugular foramen through which it passes, here it is joined by the accessory portion of the spinal accessory nerve. As it goes down the neck it lies in front of the *rectus capitis anticus* major and longus colli muscles. It passes in the carotid sheath behind and between the artery and vein. In the thorax the nerve on each side runs a different course. The *right* passes between the subclavian artery and vein, by side of trachea to root of lung, behind esophagus, through esophageal opening in diaphragm to posterior surface of stomach. The *left* passes between the subclavian and carotid arteries, in front of arch of aorta to root of lung, along anterior surface of esophagus, through diaphragm, to anterior surface of stomach. *Distribution* is shown by the various names of the branches of the nerve: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary esophageal, and gastric.

7. Scarpa's triangle is a triangular area or depression situated just below the fold of the groin. It is bounded *above* by Poupart's ligament, *externally* by the Sartorius, and *internally* by the inner margin of the Adductor longus; its *apex* is formed by the junction of the Adductor longus and Sartorious. The *floor* is formed, from without inward, by the Iliacus, Psoas, Pectineus, Adductor brevis, and Adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it is the crural branch of the genitocrural nerve. At the apex, the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

8. *Bones entering into formation of nasal fossæ:* Nasal, frontal, ethmoid, sphenoid, vomer, palate, superior maxillary, lacrimal, and inferior turbinated.

9. *Bones entering into the formation of the ankle joint,* are: The lower end of the tibia above the internal malleolus (of tibia) internally, the external malleolus (of fibula) externally, and the upper surface of the astragalus below.

10. *Viscera covered by peritoneum:* Liver, stomach, spleen, first part of duodenum, jejunum, ileum, cecum, transverse colon, sigmoid flexure, upper half of rectum, ovaries.

Viscera partially covered by peritoneum: Second and third parts of duodenum, ascending and descending colon, bladder, middle part of rectum.

PHYSIOLOGY

1. *Physiology* is that branch of science which treats of the functions of the body in a state of health.

2. "The left ventricle pumps the arterial blood through the large arteries, the small arteries, and the arterioles into the systemic capillaries. For the most part between the capillaries and the tissues is the tissue fluid, and across this the tissues acquire the oxygen from the arterial blood, and return carbon dioxide to the blood in the capillaries. The blood which leaves the tissues is venous. The venous blood returns from the capillaries through the small veins into the larger veins, and the largest veins pour the blood back into the right auricle. It will thus be seen that the right side of the heart is occupied with the pulmonary circulation, and the left side of the heart with the systemic circulation. The right auricle receives the venous blood as it returns from the tissues, and transmits it to the right ventricle. The function of the right ventricle is to pump the venous blood through the pulmonary arteries into the lung capillaries, where the venous blood becomes oxygenated. The oxygenated blood returns by the pulmonary veins to the left auricle, and the arterial blood is then received into the left ventricle."—(Lyle's *Physiology.*)

3. *Differences between the fetal circulation and that of the adult:* In the *fetus* there is direct communication from the right auricle to the left auricle by the foramen ovule; the Eustachian valves are larger, the heart is relatively larger; there is communication between the pulmonary artery and the descending aorta by means of the ductus arteriosus; there is communication between the internal iliac arteries and the placenta by means of the umbilical or hypogastric arteries; and the presence of the ductus venosus which unites the umbilical vein and the inferior vena cava.

4. *Physical composition of the blood:*

1. Plasma.
2. Corpuscles { Colored / Colorless / Platelets.

Chemical composition of the blood: Plasma consists of water and solids (proteids, extractives, fats, and salts of sodium, potassium, and calcium). *Corpuscles* consist of water and solids (hemoglobin, globulin, lecithin, cholesterin, iron, and salts of sodium, potassium, magnesium, and calcium.

5. FUNCTIONS OF THE BLOOD: The *red blood cells* carry oxygen from the lungs to the tissues. The *white blood cells:* (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some part in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper proteid content of the plood plasma. The function of the *platelets* is not determined; it is possible that they take some part in the coagulation of the blood. The *plasma* conveys nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

6. The portal system is composed of four veins (superior mesenteric, inferior mesenteric, splenic, and gastric), which collect the venous blood from the stomach, intestine, pancreas, and spleen, and conduct it to the liver.

The enzymes manufactured from its blood: "No fewer than eleven ferments have been stated to be present and active in the liver alone—viz., a proteolytic and a nuclein-splitting ferment, a ferment which splits off ammonia from amino-acids, a milk-curdling ferment, a fibrin ferment, a bactericidal ferment, an oxydase, a lipase, a maltase, a ferment called glycogenase which changes glycogen into dextrose, and an autolytic ferment."—(Stewart's *Physiology.*)

7. *The chief organs of excretion* are: The kidneys, skin, lungs, alimentary canal, and liver.

8. See QUESTION 5.

9. *Glycogen*, or animal starch, is a polysaccharide, found in the liver, muscles, placenta, leucocytes, cartilage, and other tissues. Glycogen is a source of energy and heat for the body, is a convenient method for the storage of sugar in the body, and is a possible source of fats and proteins.

10. *When a muscle is in a state of activity:* (1) It becomes shorter and thicker, but (2) there is no change in volume; (3) there is an increased consumption of oxygen; (4) more carbon dioxide is set free; (5) sarcolactic acid is produced; and hence (6) the muscle becomes acid in reaction; (7) it becomes more extensible, and (8) less elastic; (9) there is an increase in heat production and consequently a rise of temperature; (10) the electrical reaction becomes relatively negative; and (11) a sound is produced.

CHEMISTRY

1. *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing such changes.

2. (1) *Law of definite proportions:* A compound always consists of the same elements, and in the same proportions.

(2) *Law of multiple proportions:* When two elements unite with each other to form more than one compound, the resulting compounds contain simple multiple proportions of one element and a fixed quantity of the other element.

(3) *Law of reciprocal proportions:* The ponderable quantities in which substances unite with the same substanee express the relation, or a simple multiple thereof, in which they unite with each other.

3. *Three strong mineral acids:* Sulphuric acid, hydrochloric acid, nitrie acid; of these, sulphuric acid is the strongest.

4. *Alkaloids* are organic, nitrogenized, basic substances, alkaline in reaction, and capable of combining with acids to form salts in the same way that ammonia does.

They are divided into volatile and fixed alkaloids.

5. See above, PHYSIOLOGY, Question 4.

6. *Antidote for poisoning by carbolic acid* is sodium sulphate, also alcohol.

7. A physical change does not alter the *composition* of the substance; a chemical change does alter its *composition.*

8. *Organic chemistry* is the chemistry of the carbon compounds.

Inorganic chemistry is the chemistry of substances which do not contain carbon.

9. *Specific gravity* is the weight of a given volume of a substance as compared with the weight of the same volume of some other substance taken as a standard, under like conditions of temperature and pressure.

The amount of solid matter in the urine may be estimated by multiplying the last two figures of the specific gravity of the urine by 2.33 (Haeser's coefficient); the product gives the amount of solid matter in one liter of urine.

10. The formula of hydrogen dioxide is H_2O_2; it is also known as hydrogen peroxide, and as oxygenated water.

MATERIA MEDICA AND THERAPEUTICS

1. *Three drugs that will liquefy and increase bronchial secretion:* Ammonii chloridum, gr. vijss; ammonii carbonas, gr. vijss; fluidextractum senegæ, ɱxv.

℞.

Ammonii carbonatis, gr. xxxij.
Fluidextracti senegæ.
Fluidextracti seillæ, aa 3j.
Tincturæ opii camphoratæ, 3vj.
Aquæ, 3iv.
Syrupi Tolutani q. s. ad 3iv. Misce.

Signa: One teaspoonful every three hours.

2. *A diuretic* is an agent which promotes the secretion of urine.

Three vegetable diuretics: Tinctura digitalis, ɱxv; tinctura strophanthi, mviij; fluidextractum cimicifugæ, ɱxv.

℞.

Tincturæ digitalis, 3j.
Spiritus ætheris nitrosi, 3iij.
Liquoris ammonii acetatis, 3ss.
Aquæ, q. s. ad 3vj. Misce.

Signa: One ounce every three hours.

3. *Two drugs that will lower blood pressure:* Amylis nitris, ɱiij; spiritus glycerylis nitratis, ɱj.

4. *Two official drugs that will change the color of the urine:* Phenol and santoninum.

Two that will change the color of the fæces: Ferrum and bismuthi subnitras.

5. *Epinephrin* is a substance obtained from the medullary portion of the suprarenal glands of the sheep (or other animal). It is *official* under the name of Glandulæ suprarenales siccæ; dose 4 grains; *properties:* "it is a strong cardiac stimulant, slowing the pulse-rate and affecting the heart muscle in the same

way as digitalis; it is a powerful vasoconstrictor and raises blood-pressure more than any other known substance; it increases the tone of all muscular tissue; it causes diminution of peristalsis and a depression of the respiratory center, which may result in respiratory failure and death. *Uses:* In minor surgery as a local vasoconstrictor; hay fever (both internally and locally); bronchitis; bronchial asthma; congestion and edema of the lungs; cardiac diseases (here it should be employed with caution); Addison's disease; shock." —(Wilcox's *Materia Medica.*)

6. *Three drugs that may cause irritation or skin eruption:* Belladonnæ folia, gr. j; belladonnæ radix, gr. ¾; *properties:* Anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Copaiba, ɱxv; *properties:* "In small doses it is stomachic, in large ones a gastrointestinal irritant; in the process of excretion it stimulates and disinfects mucous membranes, especially those of the genitourinary tract, and on the skin it may give rise to eruptions and annoying itching. It is also diuretic, and in large amounts irritates the kidneys."—(Wilcox's *Materia Medica.*)

Cubeba, gr. xv; *properties:* "Rubefacient; irritant to the stomach; diuretic; like other volatile oils, it causes some cardiac stimulation and also stimulates the functions of the organs by which it is excreted; sometimes produces a papular or erythematous rash. Its chief action is on the mucous membrane of the genitourinary tract, which is both stimulated and disinfected by it. Its resinous acid is believed to aid the effects of the oil in its action upon the renal epithelium, as well as the bronchial mucous membrane."—(Wilcox's *Materia Medica.*)

7. *Oil of santal: dose,* 8 minims; *properties:* "Closely resembles that of copaiba and cubebs, but oil of santal is less irritant and more palatable. *Uses:* gonorrhea, gleet, cystitis, urethral hemorrhage, bronchitis."—(Wilcox's *Materia Medica.*) *Official name* is oleum santali.

8. *Elaterin: Official name,* elaterinum; dose, 1/10 grain; *properties:* "Closely resembling that of colocynth, but much more energetic, elaterin being regarded as the most powerful hydragogue cathartic known. In properly regulated doses, however, it causes comparatively little pain or irritation, notwithstanding the free catharsis produced. *Uses:* It is the most efficient of the hydragogue cathartics in general dropsy and in ascites; also used with advantage in uremia."—(Wilcox's *Materia Medica.*)

9. In *lobar pneumonia* routine treatment is to be condemned. In the first stage the following drugs may be required, under certain conditions: Alcohol, ammonii carbonas, 4 grains; quininæ hydrochloridum, gr. iv; tinctura veratri, 15 minims; digitalis, 1 grain; strychnine sulphas, 1/60 grain.

℞.

Tincturæ veratri, ɱ. xl.
Spiritus ætheris nitrosi, ʒvj.
Liquoris potassii citratis, ʒivss.
Syrupi zingiberis qs. ad ʒvj. Misce.

Signa: One tablespoonful q. 3. h.

10. *Five official tinctures:* Tinctura aconiti, 10 minims; tincture aloes, 30 minims; tinctura capsici, 8 minims; tinctura, digitalis, 15 minims; tinctura opii, 8 minims.

HISTOLOGY.

1. The *suprarenal capsules* "are two triangular flattened organs covered with fat that lie one on either side of the spine, in close proximity to the upper kidney border. Each suprarenal is invested in a fibrous capsule and a liberal supply of fat. The capsule contains many elastic fibers and some smooth muscle cells. The cortex shows a radial structure and has been divided into three zones, which are not very well defined. (1) The *zona glomerulosa,* next to the capsule, consists of a row of columnar epithelial cells folded in such a way as to form oval bodies or elongated heads separated by strands of connective tissue from the capsule. The oval nuclei are in the middle of the cells. (2) The *zona fasciculata* makes up the larger portion of the cortex and consists of anastomosing columns of epithelial cells, a continuation of the zona glomerulosa. Each column has two rows of polygonal cells that are smaller than those of the glomeruli. (3) The *zona reticularis* borders on the medulla. Here the columns anastomose and freely interlace. The cells resemble those of the fasciculata. Connective tissue cells ramify between the columns, hence the radial appearance of the cortex. The *medulla* is coarsely vascular. The cells are smaller than those of the cortex and are grouped in round or oval masses. These cells are finely granular, often pigmented, and stain a brown color. Numerous ganglion cells are present and many nerve fibers."—(Hill's *Histology and Organography.*)

2. "*Graphic reconstructions.*—Making reconstructions of this kind consists of plotting out on paper magnified representations of structures from a series of sections. Serial sections are, of course, necessary, and the thickness of the sections must be known. A camera lucida must be used and some given magnification chosen and adhered to for a particular reconstruction. Suppose, for a simple example, that a reconstruction of the stomach of an embryo is to be made. First determine the desired magnification. Then, with a camera lucida, draw on a sheet of paper an outline of a section of the stomach at its cephalic end, and, still keeping the paper in exactly the same position, draw a line to represent the median line of the section. On a sheet of drawing paper, upon which a straight line has been drawn to represent the median line of the section (sagittal plane of the embryo), measure off the distance as indicated in the camera lucida sketch, of each edge of the stomach from the median line and mark with a dot. Make the same kind of a camera lucida sketch from the next succeeding section. Plot this on the drawing paper as in the preceding case, putting the dots below, or, so to speak, caudal to the first dots at a distance equal to the thickness of the section multiplied by the magnification. Pursue the same method with successive sections, and then connect the dots that represent the edge of the stomach in the sections with a continuous line. The line, of course, represents the outline of the stomach, and, if the plotting has been properly done, it will show the relative position and general shape of the organ as seen from the dorsal or ventral side. If desired, the sketch can be shaded to represent the stomach in perspective. Drawings of two or three different structures to show their interrelation can be made in this way, so long as the structures do not become too complicated. Sometimes it is necessary to draw only from every third or fourth section."—(Bailey and Miller's *Embryology.*)

3. *Epithelial tissue* consists mainly of cells, with a small amount of intercellular substance; the cells are usually prominent and granular. The *kinds* of epithelium are: (1) *Pavement* or *Squamous:* A single layer of flat, nucleated cells, cemented together at their edges; found in descending limb of Henie's loop, Bowman's capsule of kidney, alveoli of lungs. (2) *Stratified squamous:* In layers of cells that are unlike in form, found in the epidermis, tongue, pharynx, vocal cords, vagina, anus. (3) *Columnar:* Tall, cylindrical cells arranged in a single layer; found in penile part of urethra, stomach, intestines, gall bladder, and ducts of glands. (4) *Cuboidal:* Similar to columnar, but the cells are shorter; found in thyroid gland. (5) *Ciliated:* Columnar cells with hair-like processes (cilia) on their free surface; found in Fallopian tubes, ventricles of brain, spinal canal. (6) *Transitional:* When the cells are neither arranged in a single layer like squamous, nor yet in many superimposed layers like stratified, but in two or three layers; found in pelvis of ureter, bladder, urethra.

4. "The motor endings of the voluntary muscles are chiefly from myelinated fibers. After piercing the epimysium the nerve follows the septa to the primary bundles and breaks up into fibers of which each muscle receives one; no double nerve fiber supplies many muscle fibers. The neurilemma and myelin sheath of the nerve fibers upon passing through the sarcolemma blend with it and the axis cylinder breaks into fibrillæ, each of which forms a number of bulbous enlargements that pass to a sole-plate. This sole-plate consists of a mass of nucleated, granular protoplasm, and with the bulbous nerve masses constitutes the end-plate."—(Radasch's *Histology.*)

(*To be continued.*)

Symmetromania.—M. Sternberg states that in this condition the patient has an impulse to perform certain motions in a symmetrical manner; that is, he moves simultaneously corresponding parts of both sides of the body.—*Deutsche Zeitschrift für Nervenheilkunde.*

OBSERVATIONS ON TWILIGHT SLEEP.*

BY JOHN W. BRANNAN, M.D.,

NEW YORK.

IT may seem rather out of place for a man engaged in general practice to attempt to discuss a method of conducting labor which is apparently safe only in the hands of an expert obstetrician. But there is probably no one in this room who has not been asked by his patients and lay friends what he thinks of Dämmerschlaf, and whether he would advise its general use? So much has appeared *pro* and *con* in the medical journals, not to mention the public press, that it is not easy to form an opinion on the subject. During the past few months I have had the opportunity of seeing a considerable number of cases in which this procedure was employed, and the members of the society may be interested in hearing a brief account of my observations. The cases were seen in Bellevue and its allied hospitals and were all under the care of skilled obstetricians.

In August last, Dr. W. H. W. Knipe, who has charge of the maternity service at Gouverneur Hospital, returned from Freiburg after an extended stay, strongly impressed by what he had seen there. Shortly after his return he began the practice of what he calls the true Dämmerschlaf method of Gauss, using a *stable scopolamine solution*, made according to the direction of Professor Straub of Freiburg. His cases at Gouverneur number 94, of which 55 were primiparæ and 39 multiparæ. In 70 cases complete amnesia was obtained, in 13 partial amnesia; in 2 there was analgesia. Nine cases were failures, 4 of these had only one injection. Low forceps were applied in 6 cases; craniotomy was performed in the case of a large child, the mother having a small pelvis and mitral stenosis. Had the heart been normal, Cesarian section might possibly have been done. Pituitary extract was used in 3 cases (2 of these are included in the forceps cases). Post-partum hemorrhage occurred once, moderate bleeding in a woman bearing her ninth child. Considerable excitation of the mother was noticed in two cases, attributed to poor technique; in 4 cases there was slight excitation. According to Knipe, excitation is most likely in hysterical, ignorant women, and is seldom seen in an intelligent person. There were no maternal deaths; one patient died fourteen days post-partum from double lobar pneumonia. There was one stillbirth, a case of moderately small pelvis, large child, and protracted labor, allowed too long in second stage. Two children were born asphyxiated, both lived (one of these, a syphilitic child, died later in the puerperium). There were 5 cases of oligopnea, all lived; the cord was around the neck in most of these. Dr. Knipe remarks that these statistics while good can be improved, the personal equation of the doctor conducting twilight sleep being very important if the best results are to be attained.

Dr. Knipe's dosage was as follows: The first dose consists of muriate of morphine 0.01 gm. (1/6 grain) injected subcutaneously with a record syringe; the needle is left in place and a second syringe, containing 0.0003 gm. to 0.00045 gm. of scopolamine is inserted into the same needle and injected. Three-quarters of an hour after this first injection the patient is shown some object with which the test is made; and then thirty minutes later is shown the same object. If at this time the patient remembers having seen the object before, which is usually the same, a second injection is given, consisting of 0.00015 gm. to 0.00045 gm. of scopolamine but no morphine. If at the first test the amnesia is present, which is unusual, the second dose is withheld until further tests show the return of memory. The third and succeeding injections follow at intervals of about one hour and a half according to the tests, using 0.00015 gm. or more of scopolamine as necessary. Generally it takes in all about 0.00075 gm. of scopolamine (plus 0.01 gm. morphine) to induce twilight sleep, according to Knipe. Occasionally one-half of this amount is sufficient, the one dose of morphine remaining constant.

At Harlem Hospital, where ninety-seven cases were treated, Dr. George L. Brodhead, assisted by Dr. Stein, is in charge of the service. In the first forty-six cases they employed the method of Siegel, in which the drugs are given in a routine way without the use of the memory tests, the object being to simplify the technique so that it may be used generally. The first dose consists of narcophine 0.03 gm. and scopolamine 0.00045 gm. In forty-five minutes a second dose of scopolamine 0.00045 gm. is given. In another forty-five minutes a third dose, consisting of narcophine, 0.015 gm. and scopolamine, 0.00015 gm. is given. After an interval of one and a half hours the fourth dose, consisting of scopolamine alone, 0.00015 gm. is given. The succeeding doses are given every hour and a half and consist of scopolamine, 0.00015 gm., and with every third dose narcophine 0.015 gm., so that narcophine would be given at the third, sixth, ninth dose, etc., in addition to scopolamine. Of the forty-six cases, complete amnesia was obtained in thirty-two, partial amnesia in six, analgesia without complete amnesia in five, and in two there was no effect of the drugs. The treatment was discontinued in one case after twelve hours because of the cessation of the pains. The patient was delivered twenty-four hours after the beginning of the treatment.

Nineteen of the patients were primiparæ and twenty-seven multiparæ. The average duration of labor was six hours and twenty minutes in the

* Read at a meeting of the Practitioners' Society, February 5, 1915.

primiparæ and four hours and fifteen minutes in the multiparæ. Low forceps were employed in eight cases; craniotomy was performed once, in a case of hydrocephalus. Twenty-nine of the babies cried spontaneously or after a slight delay, in fifteen there was oligopnea, but all of the babies lived, several requiring hot and cold baths, artificial respiration, etc. There were no stillbirths, but one child was born asphyxiated and one hour was required to stimulate the respiration so that the child breathed fairly well. Ten hours after birth ophthalmological examination of the eyes showed bilateral venous hyperemia of the retinal and conjunctival vessels. The baby died thirty-two hours after birth, the respiratory center having been profoundly disturbed for hours preceding death. Autopsy showed venous engorgement of the brain and all the viscera, but the cause of death was undetermined. In this case labor had lasted only four hours and the child was born spontaneously, but deeply narcotized. Brodhead states that one of the disadvantages of the Siegel plan of treatment, in his experience, is the excitement produced in some patients. On several occasions the services of three nurses were required to keep the patient in bed.

In the second group of cases, numbering fifty-one, only two-thirds as much scopolamine was used in the first two doses, viz., 0.0003 gm. and with the first dose morphine 0.01 gm. The remaining doses of scopolamine were the same as in the Siegel method, but at longer intervals (one to three hours), and no more morphine was given. The results as to the mother were fully as good as before, there being thirty-five cases of complete amnesia, seven of partial amnesia, four of analgesia, without complete amnesia and five failures, one of them due to discontinuance of the drug because labor pains stopped. There were, however, several cases of undue excitement requiring restraint by several nurses, as under the Siegel method.

Twenty-seven of the patients were primiparæ and twenty-four multiparæ. The average duration of labor was about the same as in the first series. Forceps were used in five cases, and one case of twins required version. The babies fared better under the smaller dosage, forty-two being born with spontaneous cry or slightly delayed, and only nine having oligopnea. One child, a premature infant, was asphyxiated at birth. Two babies died in the puerperium, one of syphilis, the other of atelectasis, the child having but one kidney.

At Bellevue Hospital, including the School for Midwives, twenty-five cases were treated in the service of Dr. J. Clifton Edgar. The technique and drugs were the same as carried out and used at Freiburg. Narcophine and scopolamine hydrobromide were used in every case. Complete amnesia was obtained in eleven cases, partial amnesia in eight, in four cases the result was indefinite and they were classed as failures. According to Edgar, all the stages of labor were lengthened, which he considers due to the effect of the drug. It was necessary to employ forceps in only one instance. No dangerous symptoms were observed in the mothers. In one patient marked delirium followed the first and only dose. No especial tendency to postpartum hemorrhage was notice in any of the cases. As to the babies, fourteen were born apparently in excellent condition and cried promptly and spontaneously. Nine were born with varying degrees of cyanosis and asphyxia which required attention to set up respiration. All lived.

Edgar adds that the subsequent condition of the mothers was excellent. There was never any persistence of the mental excitement or delirium when these followed the first injection.

Dr. John H. Telfair, the obstetrician at Fordham Hospital writes that he has "personally conducted two cases of 'Dämmerschlaf' at Fordham, staying with the case from the first injection until delivery. The first case was a complete success; the second a total failure. Both babies cried at once and were otherwise normal."

In the four hospitals 216 cases in all were treated. In 149 of these, or 69 per cent., complete amnesia was obtained; in thirty-five partial amnesia, or 85 per cent. in which amnesia was wholly or partially complete. In eleven cases there was analgesia, and twenty-one, or 9.7 per cent. were failures. Low forceps were applied in twenty cases, or 9.3 per cent., not far from the usual rate. It should be noted that eight of these were among the forty-six cases in which the Siegel method was employed, a method which is now generally abandoned by the advocates of twilight sleep. In the 191 cases at Gouverneur and Harlem there were twenty-nine cases of oligopnea among the babies, but here again the Siegel method was largely responsible, fifteen of the twenty-nine being among the forty-six cases treated without the use of the memory tests.

Dr. Knipe has also introduced a system of exercises which he brought with him from Freiburg. They are begun about twelve to eighteen hours after delivery and are as follows:

Time.—Begin about twelve to eighteen hours after delivery and perform twice daily.

Frequency of Movements.—The first time they should be passively executed by nurse, each movement ten times. After that actively and *against resistance,* which should be increased from time to time.

Upper Extremities.—1. Flex wrist—hand on forearm.

2. Flex forearm—on arm.

3. Flex arm across body—elbow stiff.

4. Circle with arm—forward and backward, elbow straight.

Lower Extremities.—1. Flex ankle—on leg.

2. Flex ankle on leg—leg on thigh and thigh on body—bringing knee to chest and grasping with both arms—clasp to chest; straighten leg to right angle to body and point toe, and then lower gradually to floor. (Do not drop leg suddenly).

3. Toe pointing and knee stiff, lift leg from floor to right angle to body; each ten times, then both together. (Do not drop suddenly.)

4. Toe pointing and knee stiff—abduct leg as far as possible.

5. Toe pointing and knee stiff—circle with each leg.

6. Flex knees bringing feet close to buttock; separate knees against resistance, as far as possible.

7. From position resulting from Exercise 6, bring knees together against resistance.

8. Same position as 6; lift hips from floor as high as possible; return to floor gradually. (Do not drop.)

Trunk Exercises.—1. Arms straight at side—nurse holding feet down—come to sitting position and bend forward *from hips.*

2. Arms folded on chest—repeat Exercise 1.

3. Arms clasped behind head—repeat Exercise 1.

Remarks.—After first few days exercises are best given on firm unyielding surface—comforter on floor is best, unless very firm couch is at hand.

Other exercises of benefit later, not a part of the Freiburg exercises: 1. Lying on face—toe pointing and knee stiff—raise leg from floor as high as possible.

2. Lying on back—raise whole body on heels and shoulders. Lying on side forearm at right angles to arm and elbow just beneath shoulder—raise body on ankles and elbow.

3. Lying on face—clasp hands behind back, elbows stiff, and raise chest from floor as far as possible. Helps to restore lumbar curve and strengthens back muscles.

In Freiburg they have a system of hydrotherapy consisting of alternate hot and cold douches and sprays to the body, especially abdomen, begun about ten days after labor. These are taken lying on a support in bath tub.

I have seen some of the above exercises taken by the patients and the interest of the women is remarkable. They watch and follow the nurse as closely as children watch the teacher in school exercises and in folk dances. It is claimed that by this means patients retain a better muscular condition and are able to get up on the third or fourth day. Some were sitting or standing about who had been delivered six or seven days previously. They are allowed, if they wish, to go home on the eighth day instead of on the twelfth, as formerly. After leaving the hospital the patients are visited by the social service nurses who have found, as a rule, that the patients have done well at home. Dr. Cooke, the house physician, a very intelligent observer, believes that the exercises favor the contraction of the uterus which occurs more rapidly and thoroughly, and if the uterus is well contracted by the eighth day the patient is discharged. Obstetricians of large experience to whom I have spoken believe that it is impossible for the uterus to contract into the pelvis by this time. It should be added that the exercises are not limited to the twilight sleep cases; all the patients in the service have the benefit of them.

I have seen several women in twilight sleep and from twenty to thirty cases after delivery. I have also seen the babies, including some that had suffered from oligopnea, and they all appeared flourishing. At Freiburg, I am told, they do not pay much attention to this condition, leaving the baby to come out of it spontaneously, and maintaining that the child is none the worse for it; but physicians here do not like it and make efforts to stimulate respiration. Inertia of the uterus is one of the contraindications of scopolamine, and the treatment should never be begun until there are definite signs of labor with pains recurring at regular intervals. The doctor should be with the mother from the time the drug is administered until delivery is complete. The patient must be in a quiet, preferably darkened, room. At Gouverneur one or two rooms are set aside for these cases. In Harlem Hospital I talked with a woman in the intervals between the pains and she responded quite naturally, but remembered nothing of the labor afterward. Dr. Knipe thinks that hospitals should be provided for ward patients where they can have a specially trained nurse and house staff in attendance. Under these conditions the treatment would be a great resource to many people.

I have felt obliged to go into this new method of treatment because it was being used so extensively in some of our hospitals. I should not, however, wish to express a final opinion until I have data from several hundred cases. At present I do not see anything to contraindicate the treatment in selected and well-conducted cases. In my judgment, however, it cannot safely be employed by the general practitioner, but should be restricted to specialists.

48 West Fifty-First Street.

PROPAGATION OF PURE VACCINE VIRUS.

By Hideyo Noguchi, M.D.,

New York.

(From the Laboratories of the Rockefeller Institute for Medical Research.)

An ideal vaccine preparation should possess sufficient potency to insure a successful vaccination in cases in which there is no immunity, and at the same time be free from secondary bacterial contamination. The prevailing method of vaccine preparation in the present day consists in collecting at an appropriate moment the virus from the vaccinal eruptions on the skin of the calf and then subjecting the raw material to the bactericidal effects of certain chemical reagents (glycerin, phenol, etc.), which do not impair the virus itself to a serious extent. By this treatment the contaminating bacteria are so reduced in number and kind that the material is now considered ripe for practical use. The method requires stringent precautions in order to produce a model vaccine, and no product is regarded as ready for use before it has been left in contact with the chemical (glycerin) for a month or longer. It is evident that much labor and care can be spared if a method is found by means of which the virus can be propagated directly free from bacterial contamination.

This problem has engaged my attention for the past year and I have now succeeded in propagating pure vaccine virus in the testicles of the rabbit and calf which is absolutely free of bacteria and preserves its virulence undiminished.

The testicle of the rabbit has been employed in recent years for the cultivation of spirochætæ—the *Treponema pallidum* and *Treponema pertenue*, and the effects upon the organ of the inoculation of the usual vaccine virus have been studied slightly. A review of the literature on that aspect of the subject will be given in our full publication. Suffice it to state here that the few experiments performed did not have in view the preparation of pure vaccine for practical use in vaccination.

The essential first step is to have for inoculation into the testicle a vaccine virus quite free of bacteria. This was secured by inoculating the carefully cleansed and shaved skin of the rabbit with glycerinated virus, protecting the vaccinated surface with sterile gauze, collecting the skin vaccine at the height of the eruption, and, spores and spore-bearing bacteria having been thus excluded, emulsifying it in sterile salt solution and treating the emulsion with pure ether or with phenol in appropriate concentration. Non-spore-bearing bacteria may thus be killed without seriously impairing the strength of the virus. Vaccine virus containing bacteria is unsuitable for testicular inoculation, since the inflammation which ensues favors the growth of the bacteria at the expense of the virus.

On the other hand, when the virus devoid of bacteria is inoculated into the testicle it multiplies very much as it does in the skin, so that on the fifth or sixth day maximal growth has been obtained, after which, as the immunity rises, the multiplication falls off and, ultimately, the virus disappears.

Hence, the testicles are removed at the proper moment and employed, in part, for reinoculation.

But not every strain of vaccine virus can be transmitted to the testicles, and, also several successive testicular inoculations are required in order to adapt even a favorable strain to the testicular growth. Once adapted, the propagation in the testicle seems to proceed as regularly as in the skin.

When the virus has been adapted to the testicle of the rabbit it can next be adapted to the testicles of young bulls. Several successive inoculations are required also in this latter animal in order to obtain virus of high activity.

The testicular cultures of vaccine virus exhibit all characteristic properties of the skin-propagated virus. The two varieties of virus are indeed indistinguishable in their action upon the skin and cornea of rabbits and the skin of calves. Moreover, the rabbit testicular strain of the virus, free from all bacteria, produces typical vaccinal effects in human subjects in whom are eliminated the secondary local and general reactions due to bacterial association with the skin virus.

The full paper dealing with this subject will appear in a forthcoming issue of the *Journal of Experimental Medicine.*

CHRONIC DILATATION OF THE STOMACH.*

A CLINICAL AND EXPERIMENTAL STUDY.

By W. HOWARD BARBER, M.D.,

NEW YORK.

(From the Laboratory of Experimental Physiological Surgery and the Gastro-Enterological Dispensary of New York University, and the Division of Gastro-Enterological Surgery of the Polyclinic Hospital.)

DISTENTION[1] is a physiological increase in the size of the stomach. Acute dilatation[2] extends over a few days, and follows inflammations and injuries of the brain, nerves, or stomach muscle. Chronic dilatation is the end result of a gastric overload, and extends through a period of months and years. Fagge, in 1873, states, "Dilatation of the stomach, independent of obstruction at the pylorus or in the small intestine, is a condition which has long been recognized," and Mayo,[3] in 1903, reports twelve cases of chronic dilatation without obstruction.

Osler[4] considers the stomach "absolutely dilated" when the capacity exceeds Ewald's normal of 1600 c.c. Delay is frequently present. Indeed, Mayo considers the most valuable evidence of the test breakfast to be the presence or absence of raisins swallowed at the preceding evening meal. Prior to the introduction of the *x*-ray he had concluded that the retention of raisins over night was in certain cases ample justification for exploratory laparotomy. Nevertheless, laboratory studies of the gastric contents, especially when pursued by the fractional method,[5] are of scientific interest, if not often of confirmatory value. Of essential morphological value is the information obtained from an examination of a stomach section, if only of the seromuscular wall of the stomach, though it is recognized that opportunity for obtaining such material is infrequent. Properly seried roentgenograms are of course of confirmatory value in defining the stomach and estimating its functions in terms of the bismuth meal. The *x*-ray standard fixes the intercristal line in the dorsal prone and 4 cm. below that line in the upright positions as the caudal limit of extension of the greater curvature of the stomach, and allows six hours for discharging its contents into the intestines.* Therefore, sag and inertia as detected through the *x*-ray are inferential evidence of increased load, or decreased prostaltic power. Finally three important symptoms in long standing cases are abnormal holding capacity, retention, and sag, any two of which, for general purposes are sufficient to make a most probable diagnosis of atonic dilatation.

Etiologically dilatation appears to be the primary equivalent of two opposing dynamic forces, namely, contractility and distention. On this basis any factor decreasing the prostaltic or increasing the resistant powers of the stomach is causal in chronic dilatation. Among such factors may be mentioned, on the one hand, prolonged toxemias and infection, general bodily overwork, insufficient nourishment, and unhygienic surroundings; and on the other hand, habitual overeating and overdrinking, and mechanical obstruction. Glenard's gastroptosis and the water-trap stomach, recently described by Satterlee and LeWald,[7] by lengthening the pyloric arm and prolonging the exposure of the stomach wall to the toxic material, probably both retard and impair normal gastric emptying.

Huntington,[8] in his comparative anatomical studies, states "in animals whose bodies are long and slender, as in most saurians, many teleosts, the stomach is likewise usually long and slender in shape, unless special modifying conditions exist." This influence of shape and size of the abdominal cavity would therefore account for the vertical position of the adult human stomach, but its dilatation, according to the same author, is an acquired character, the resultant in part of the habitual amount of food required and the volume and digestibility of the food. This probably explains the incidence of gastric ptosis with dilatation in the individuals of two or more successive families. It has been strikingly illustrated to the author in the "M" family (referred to the author through kindness of Dr. B. P. Farrell), in whom the grandmother, two daughters and one grandson have been found to have dilated ptosed stomachs, and also in the "S" family (referred to the author through kindness of Dr. G. R. Satterlee), in whom mother and daughter were incapacitated for the same reasons.

Physiologically, therefore, dilatation appears to be the dynamic resultant of work and load, with the balance in favor of the load. Such a state is usually acquired, but often predisposed to by torsal malformations, which are apt to be accompanied by a vertical stomach.

Experimentally an attempt has been made to increase the pyloric resistance in thirteen dogs' stomachs, and study its effect upon each stomach wall after a certain lapse of time. The pyloric mucous outlet was resected one-half in eleven dogs and the pyloric arm lengthened twice by anchoring the stomach 8 cm. cephalad to the pelvic brim in two dogs. All were allowed to live from one to eight weeks before being submitted to gastroenterostomies. In each case but two the stomach was found dilated. These were a normal stomach and a stomach grossly hypertrophied and freed from its new attachments in caudad abdomen. The pylorus was found patent in each case. It was possible in several of the artificially stenosed cases, even though, as generally happened, firm adhesions were found

Read before Ex-Interne Society of M. E. (Seney) Hospital, March 25, 1915.

*Standard used at the Gastroenterological Clinic, N. Y. U.

about the pylorus, that the pyloric canal had regained normal size. In view of this overwork it appeared certain that at least a functional if not a structural change had occurred in the gastric wall, probably in the musculature, possibly in the elastic tissue, as suggested by Dr. Alexander Fraser. In each of the stomachs there were noted pallor and deficiency of blood supply, absence of rugæ, giving the stomach an ironed out appearance and thinned out walls. To date no constant muscular or elastic tissue change has been discovered microscopically in any of the above dogs' stomachs, but retention of stagnant fluid and indigestible material have been frequently observed. Mayo-Robson,[9] on the other hand, speaking of the pathology of human dilated stomachs, gives: "(a) Degeneration of muscle (fatty, colloid), (b) want of nerve tone, or paresis, (c) organic disease of the muscle due to fibrosis." Therefore, it appears that a stomach may be clinically dilated and still show no pathological tissue change in its muscular fibers.

177	42	Pyloric antrum	Stomach contracted at necropsy)	
228	0	Pyloric antrum	Percentages not obtained. Greater amount of fluid resembling fluid found in stomach in loop from pylorus	
224	0	"Pendant"	Percentages not obtained. Greater amount of fluid resembling fluid found in stomach in loop from pylorus	
232	0	Pyloric antrum	80	20
226	0	Pyloric antrum	90 9	9 1
227	0	"Pendant"	99	1
242	0	Pyloric antrum "Pendant"	Stomach dilated. Most of milk curd found in loop from pylorus, less in loop from pyloric stoma, and least in loop from pendant stoma	

The treatment, as pointed out by Kaufman,[1] "will depend to a much greater extent on our ability to regulate the patient's mode of living and on the patient's ability to observe general hygienic and dietetic principles and rules, which consider not only his local disorder, but in the broadest possible way his constitutional make up, his mental state, his work, and his habits." Nevertheless, when this course fails, as it occasionally does for economic and other reasons, recourse may be had to surgery with some hope of hastening relief, if not recovery, from symptoms.

The surgical therapeutics of this affection appear to lack standardization. The methods pursued are as diverse as are the notions of the principles of its surgical physiology. Hence plication, suspension, or fixation, resection by knife, or suture, and gastroenterostomy have been recommended. W. J. Mayo[2] reports most success with plication combined with Finey's gastroduodenostomy. Mayo-Robson[9] favors gastroenterostomy alone. Gastroenterostomy seems best to meet the indications of relatively increased resistance or insufficient emptying power. It has been studied in the laboratory and in the light of experimental findings applied clinically.

Experimentally an effort has been made to study the comparative efficiencies of pyloric and "pendant" stomata in gastroenterostomy for dilated stomach. To this end sixteen dogs have been used. Of this number seven underwent artificial pyloric obstruction for twenty-three to fifty-eight days. In each of fourteen posterior gastroduodenostomy was done. In two double posterior gastroenterostomies were performed. The stoma was made 3 cm. in diameter. Five to eight days later, under morphine-ether anesthesia, the loops at approximately equal distances aboral to pylorus and stoma, respectively, were loosely ligated with gauze. One day later the dogs were fed 30 c.c. milk. At the end of one hour each dog was killed and contents of the loops were weighed. Glass beads were substituted for milk and counted in a few animals. Resection instead of ligation was performed in four dogs.

From a study of Table No. 2 it appears that the pylorus is the most efficient outlet from the gastroenterostomized (or otherwise normal) dog's stomach, and that, other factors being normal, the closer the artificial opening coincides with the physiologic opening, the greater becomes its efficiency as a stomach outlet. However, of these factors, muscle tone is vitally important, and probably variable clinically, especially in instances where gastroenterostomy is indicated. Dog 113, Table No. 1, was noted as "dilated," and after a stoma was placed most suitable for "pendant drainage" it became 88 per cent. efficient. This was not true, however, of dog 205, with a previously normal stomach, whose "pendant" stoma was but 37 per cent. efficient.[12] In each case in which double gastroenterostomy had been performed acute dilatation was found; the character of the intestinal contents, however, indicated that over two-thirds of the stomach contents left the stomach after passing through the pyloric antrum.

Clinically two human cases are typically noteworthy; one a recurrent total failure under medical treatment, and the other a comparative failure from prolonged medical treatment and a Coffey suspension operation.

Case I.—J. L., age 28. Symptoms for eight years. Complained of constant pain in the pit of his stomach, without reference to eating. He has *eaten* bicarbonate of soda, vomited, and in this way relieved "heaviness" in stomach, two or three times a week for the past year. Said he vomited one or more quarts, and noticed remnants of food eaten one or two days before. Headache and constipation. Lost eight pounds in six months. Negative Wassermann. Had been treated

*For Pathological Findings see text.

†Stomach had freed itself from its attachments and returned to normal position and size.

medically for the past two years, with three recurrences. Signs were those of gastrocoloptosis. *X*-ray (Fig. 1) showed marked sag, increased size, and retention of the stomach. Was operated upon October 19, 1914. Appendix pale and atrophic, removed, stomach large and thin-walled. Posterior gastroenterostomy performed with stoma in pyloric antrum. No ulcerated area was actually seen but the pylorus seemed to be the site of induration, because it barely admitted the tip of the index finger.

FIG. 1.—Case I.

FIG. 2.—Case I.

November 13, 1914. Entirely free from pain. Has much gas and stomach feels "heavy." Occasional headache, less constipated. Vomiting less. January, 1915. Reports free from pain, heaviness and vomiting.

CASE II.—J. O., woman, age 47. Had symptoms for twenty years. Complained of pain and heaviness in epigastrium, relieved by vomiting, which she brought on at least twice a week. Insomnia, headache, constipation, and loss of weight.

She had a narrow subcostal angle with ptosed stomach, liver and kidneys; urine and feces negative. Roentgenogram, as illustrated, showed ptosis of the stomach and delayed emptying. Was treated medically without any appreciable improvement for months.

March 30, 1914. A chronically inflamed appendix

FIG. 3.—Case II.

FIG. 4.—Case II.

was removed, a Jackson's veil divided, pyloroplasty and a Coffey suspension operations were performed. The plastic was done not to widen the pylorus, but to allay the suspicion of ulcer at the pylorus. The pylorus was contracted so as to admit but the tip of the index finger, and the walled up mucosa, as in previous case, gave sensation of indurated area. Not only was the pyloric opening perfectly smooth when felt through the incision and the pylorus itself relaxed to three fingers,* but the section removed from the suspected area was absolutely negative. This patient was carefully followed for the next nine months. Although she gained eighteen pounds and felt generally improved she was not free from headache, constipation and occasional nausea. Roentgenograms showed stomach up, but with residue. January 11, 1915, gastroenterostomy was performed with "pendant" stoma. The result to date has been all that could be looked for. Taste and appetite have returned for the first time in over ten years. The metallic taste has disappeared. She eats everything, and has gained seven pounds in the first week from the hospital. Bowels move freely twice a day without cathartic. Insomnia has entirely disappeared.

FIG. 5.—Case II.

From a review of these cases it appears that medical treatment alone as well as medical treatment assisted by suspension were inadequate for the complete symptomatic relief of these chronically dilated and atonic stomachs; that gastroenterostomy secured at least to date this relief, which was gradual (three months), with the stoma in the pyloric antrum, and immediate (three weeks) with the opening in the "pendant" stomach. Regeneration of the atonic musculatures is questionable, and what effect such a stomach improvement may continue to have on the comparative efficiency of the two artificial stomata remains to be proved.

"One understands," writes Professor Hartmann,[13] "that the juxtapyloric anastomosis works actively when the pylorus is normal, and that the anastomosis in the cardiac part is functionless in cases of permeable pylorus." It appears, however, that a "pendant" stoma works actively in the presence of a permeable pylorus when the stomach is dilated, or its muscle-emptying power is pathologic. Dilatation undoubtedly occasionally exists where gastroenterostomy is indicated, and should, of course, be carefully estimated before placing the stoma. Pendant drainage in presumably pathologic stomachs is well illustrated by A. Ogarkow,[14] who compared the dried stomach residues removed by stomach tubes after submitting the patients to various postures. He found 19.5 per cent. of the test breakfast remaining in the stomach after an hour's lying on the right side, while in the prone and upright positions for the same time it rose to from 25-34 per cent. Similarly Jefferson,[15] in studying the Canalis Gastricus in the human stomach noted that when bismuth cream enters the stomach it is confined to the lesser curvature in 82 per cent. and in 18 per cent. "it spread rapidly over the sides of the stomach." "These stomachs," he observed, "were atonic, though healthy—a combination by no means rare." The importance of gravity on gastric emptying in respect to the dilated and atonic stomachs must therefore be reckoned with medically, and in those few cases in which surgical aid is sought it should influence the localization of the stoma.

Conclusions.—1. Chronic atonic dilatation, etiologically and therapeutically considered, is a problem in pathological physiology.

2. Most cases are amenable to medical treatment. Many are relieved by suspensions. Of both of these classes many are entirely correctable physiologically by carefully planned gastroenterostomies.

3. The position of the stoma is vitally important and depnds on the following: (a) For normal or hypertrophied stomachs the pylorus is the most efficient outlet. (b) For normal or hypertrophied stomachs the nearer the artificial stoma corresponds with the physiologic point of outlet the greater is the efficiency. (c) For "moderately" atonic stomachs or stomachs with 50 per cent. impaired prostaltic power, the efficiency of the stoma is probably greatest in the pyloric antrum, while (d) for the markedly atonic stomachs, with pronounced muscular insufficiency, the pendant stoma seems to date most efficient.

*Complete pyloric relaxation following marked stenosis has been noticed in stomachs of dogs under deep narcosis. The difficulty of deciding positively on duodenal ulcer even on the operating table, is well shown in these two clinical cases.

AMERICAN THERMAL SPRINGS:

THEIR THERAPEUTIC USES: RADIOACTIVITY OF SPRINGS IN GERMANY, AUSTRIA, AND VIRGINIA; WITH A REGIME FOR PATIENTS WITH GOUT, RHEUMATISM, AND ARTHRITIS.*

BY GUY HINSDALE, A.M., M.D.,

HOT SPRINGS, VA.

SECRETARY OF THE AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION; FELLOW OF THE ROYAL SOCIETY OF MEDICINE, GREAT BRITAIN, ETC.

BALNEOLOGY is the scientific medical study of bathing and medicinal springs (Oxford Dictionary). Balneology is a part of the larger science of medical hydrology which is that department or division of medical science which treats of the use of waters, especially mineral waters, for therapeutic purposes (Foster's Encyclopedic Medical Dictionary). Hydrotherapy is a term usually applied to the use of ordinary water, not necessarily mineralized, for medical treatment; but of late there is a tendency to enlarge the application of this word so as to include balneology as well.

Thermal springs are those having a temperature above that of the mean annual temperature of their locality; but for convenience it is arbitrarily assumed that this temperature is 70° F. or over. Between that and 98° F. they are warm springs; above that they are hot and may reach the boiling point. They originate in far deeper geological formations than in the case of ordinary cold springs occurring in more recent sedimentary strata. This has a bearing on the composition of thermal as contrasted with non-thermal springs; for example, Mount Clemens, Mich., or Saratoga Springs, N. Y., as compared with Virginia or Arkansas Hot Springs.

*Read at a special meeting of the Philadelphia County Medical Society on Hydrotherapy, January 29, 1915.

The two former are heavily charged with sodium chloride from recent sedimentary and more soluble formations, while not one grain in a gallon of this particular salt is found in any of the Virginia Hot Springs.

It is interesting to note that radium is present in the Cold Springs of Saratoga, in the Hot Springs of Virginia and Arkansas, and in numberless springs of the Yellowstone National Park, as well as in Colorado and California.

To derive any benefit from the radioactive qualities of mineral springs they must undoubtedly be used at their source, directly on their emergence from the ground or used in a bath house not too far distant.

The following list, though incomplete, gives some idea of the distribution of thermal springs in the United States:

	Temperature, Deg. F.
Lebanon Spring, Columbia Co., New York	75
Spring near Carlisle, Perry Co., Pennsylvania	72
Rockbridge Baths, Virginia	74
Sweet Chalybeate, Alleghany Co., Virginia	75
McHenry's Thermal Spring, Scott Co., Virginia	68
Healing Springs, Bath Co., Virginia	84
Warm Springs, Bath Co., Virginia	96 3
Hot Springs, Bath Co., Virginia	106
Berkeley Springs, Morgan Co., Virginia	74
Sweet Springs, Monroe Co., West Virginia	79
New River White Sulphur, Giles Co., West Virginia	85
Hot Springs, Buncombe Co., North Carolina	92–117
Citadel Green, Charleston, S. C.	99.5
Warm Springs, Meriwether Co., Georgia	70– 90
Livingston Spring, Sumter Co., Alabama	68
Bailey's Springs, Alabama	72– 80
Hot Springs, Arkansas	46–147
Hot Springs, South Dakota	98
Liberty Hot Springs, Colorado	140–150
Hot Springs, Canon City, Colorado	162
Hot Sulphur Springs, Middle Park, Colorado	110–117
Glenwood Springs, Colorado	124
Idaho Springs, Colorado	106
Las Vegas Springs, New Mexico	110–140
Hudson Hot Springs, New Mexico	142
Ojo Caliente, Taos Co., New Mexico	90–122

West of the Rocky Mountains thermal springs are too numerous to mention; this is particularly true of California and the Yellowstone National Park.*

FIG. 1.—Spout bath, or fixed warm douche.

The thermal springs in the mountains of Virginia, Arkansas and elsewhere are derived ultimately from deep rocks of volcanic or igneous origin, but in connection with faults or profound dis-

*See Radioactivity of the Thermal Waters of Yellowstone National Park. Schlundt and Moore, Bulletin 395, U. S. Geological Survey, Washington, 1909.

locations with corrugations of the overlying strata.

In one of the narrow valleys of Virginia where the Blue Ridge and Alleghany mountains approach each other there is a group known for nearly one hundred and fifty years as "The Hot," "The Warm" and the Healing Springs." The mountain ridges on either side have an elevation of 3,500 feet to 3,700 feet and are 1,200 to 1,400 feet above the valley. They are all within a radius of five miles. The combined discharge at Hot Springs is about 300,000 gallons and at Warm Springs about 1,700,000 gallons in twenty-four hours. The early records of the "Boiler Spring" used for bathing at Virginia Hot Springs show that the temperature of 106 F. has been constant since the first observations published in 1804.

To raise the temperature of a water supply artificially, or to lower it in the case of very hot thermal springs, introduces an element needing human control, and this factor is not always uniform. The process of heating waters artificially tends to drive off the contained gases and the radium emanation along with them, and in so far as this is accomplished, one would lose some of the natural qualities of the water. Of course, the solids in solution would not be affected by such manipulations.

Fifteen springs at Hot Springs, Warm Springs and Healing Springs, Virginia, were tested for radioactivity at their source in July, 1913, by Profs. Ernest Zueblin and J. C. Hemmeter, of the University of Maryland. They used the fontactoscope of Engler and Sieveking, and their table shows the results in mache units. It is evident that the radioactivity is high. Healing Springs is thus intermediate between Kreuznach and Baden Baden; Warm Springs, higher than Baden Baden; the Hot Sulphur Spring, higher than Gastein; the Boiler Spring and Magnesia Spring higher than Landeck and Gastein.

Mache units in a bath of 200 liters, including the values for water, gas and dry residue combined:

	In 200 Liters	In 1 Liter
Radium Kurhaus, Joachimstal	120,000	600
Magnesia Spring, Hot Springs, Virginia	56,800	274
Boiler Spring, Hot Springs, Virginia	42,800	214
Landeck, Silesia, Germany	40,000	200
Hot Sulphur, Hot Springs, Virginia	31,400	157
Gastein, Austria	30,000	150
Warm Springs, Virginia	26,800	134
Baden Baden, Germany	25,000	125
Swimming Pool, Hot Springs, Va	21,854	109
Healing Springs, Virginia	17,284	86
Kreuznach, Germany	11,200	56
Nauheim, Germany	5,720	28
Pistyan, Hungary	4,680	23
Soden, Taunus, Germany	4,400	22
Neundorf, Prussia, Germany	4,000	20

The values given above are taken from Professor Zueblin's paper (*vide infra*). Published data may vary greatly and there is much confusion as to units, etc. Strong radioactive springs may be taken to include those having at least 100 mache units per liter; medium, with 50 to 100 units per liter; and weak springs with 20 to 50 units; in quantities less than this the radioactivity is probably too little to designate them as such. We are yet unable to say how the radium emanation of mineral springs affects the human organism when they are used as baths or as drinking waters. European observers attribute great value to the radioactive waters, especially in disorders of metabolism, such as gout and rheumatism. That it is an asset of value is undoubtedly true and it has been seized upon as explaining many of the difficult problems of balneology. Radium is too elusive an element, at least its emanation is too elusive, to isolate its influence in a given case undergoing balneologic treatment. *Post hoc non ergo propter hoc* should always be kept in mind in drawing conclusions.*

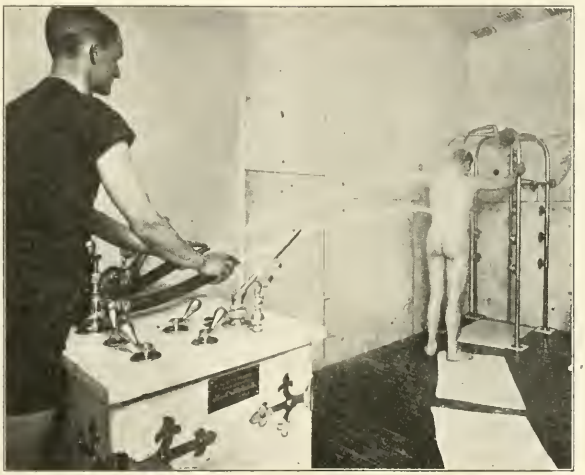

FIG. 2.—Scotch douche. The jets of warm and moderately cool water are passed alternately down the spine for 15 to 20 seconds.

*The connection of hot and warm springs with volcanic rocks, with uplifted mountain chains, and with dislocations of strata has long been recognized. The source of heat is believed to be great masses of igneous rock intruded in the earth's crust by volcanic agencies. Deep seated waters converted into vapors by contact with this heated mass probably ascend through fissures toward the surface where they meet cold springs which are heated by the vapors.—J. K. Haywood, Laboratory, U. S. Dept. Agriculture.

*For "The Present Status of Radioctive Therapy in Medicine" with a bibliography of 263 references to the recent literature, see Ernest Zueblin, *Maryland Medical Journal*, May-June, 1914. See also Radiological Bulletin published by the Kreuznach Medical Society, 1914.

The time-honored methods of treating gout, rheumatism, arthritis, syphilis, skin diseases and many other chronic affections include the use of tub baths, douches, douche-massage, packs, cabinet baths and various manipulations. At all mineral spring resorts there are certain specialties of treatment, as, for example, the famous douche-massage at Aix-les-Bains, the Plombière douche, the spout baths at Hot Springs, Virginia, and the special antisyphilitic methods used at Aix-la-Chapelle and Hot Springs, Arkansas. The therapeutic differentiation of mineral springs commonly recognized in Europe has not yet been so well defined in America, but there have already been slight indications of this. Gout, rheumatism and arthritis are treated at all thermal springs, especially at those in Virginia, Arkansas and California. Syphilis is treated extensively in Arkansas and at Mt. Clemens, in Michigan. Cardiac cases, by means of "Nauheim" or carbonated baths at Glen Springs and Saratoga Springs, New York. At these places special provision is made for the affections indicated.

Recently attempts have been made to standardize physical therapeutics.* This has met with some success in general electrotherapeutics and especially

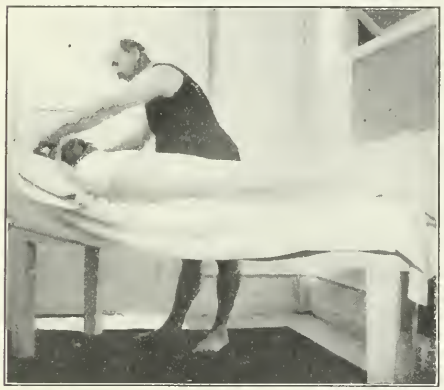

Fig. 3.—Hot Dry Blanket Pack. Adjusting cool cloth to the head.

in using the *x*-rays and radium, light and heat. Mechano-vibration, massage and Zander exercises lend themselves rather well to something approaching a standard method of treatment, although, of course, individualization is always highly necessary to success in any case. Whether balneology and hydrotherapy can be included in any standardized system remains to be seen. It probably is to some extent possible.

We may incidentally mention here a fact commonly noted in the use of thermal baths in the case of patients having gout and rheumatism, and that is that a painful reaction is liable to ensue at some time in the course of treatment. This has been noted in very early times and is familiar to physicians who have anything to do with thermal springs. As far as I know this painful reaction does not occur in treating other affections as, for example, in the use of carbon dioxide baths for cardiac disease. The occurrence of this reaction is, in a way, encouraging—at least for the physician—and may be taken as an indication that the disease is being dislodged, painful though it may be. In "King John" Shakespeare says:

"Before the curing of a strong disease
Even in the instant of repair and health,
The fit is strongest; evils that take leave
On their departure most of all shew evil."

More than one hundred years ago Rev. Dr. Ashbel Green noted that patients at Virginia Hot Springs experience temporarily, while under treatment, an aggravation of their symptoms. Of one of the patients he says: "He used the waters . . . . and for nearly two weeks he complained that he rather grew worse than better. At length, however, his pains left him so suddenly that he could scarcely believe they were gone. The pains did not return and the patient went away well."

The obvious lesson from this is that it is wise to forewarn our patients of such a possibility and thereby disarm criticism. If nothing is said in advance our explanations may carry little comfort, the patient seems incredulous and discouraged.

Cases of acute gout and rheumatism are usually better treated at home and should probably be spared the discomforts of long railway journeys, especially the dangers of a trans-Atlantic voyage. So, also, patients with cardiac disease, especially if uncompensated, should not be sent on the long trip to Nauheim, even were that spa able to receive them as in times past. Circumstances render it necessary to look elsewhere and Americans are now learning to make use of their own resources. We have already briefly mentioned some of the specially indicated American spas.

Experience at the Hot Springs, Virginia, and observation at other spas where patients come for the relief of chronic gout, rheumatism, arthritis, fibrositis, and kindred maladies lead to reliance on the following measures, modified according to individual resistance and susceptibility:

1. A tub bath at 102°, 103°, or 104° F. Vigorous (or gentle) rubbing in the tub, especially of affected joints or other areas. Duration of bath, 6 to 12 minutes.

2. The hot, dry pack. The patient on emergence from the tub is instantly wrapped in a hot and dry sheet, laid on a couch where he is closely enveloped in hot, dry blankets, care being taken as the three or four successive blankets are applied to leave no chance for the entrance of outside air. Duration of pack, 10 to 25 minutes.

3. Cloths wet in ice water to be applied to the head while the patient lies in the tub and in the pack.

4. After the pack a douche of cold water all over the body; or, in more delicate patients a sponge dipped in cool water applied quickly two or three times up and down the spine.

5. A more or less vigorous rubbing all over the body for five to eight minutes with pure alcohol; where, on account of the condition of the skin, alcohol is contraindicated, cocoanut oil may be used.

6. After three successive baths a day of rest.

7. As an additional measure to institute on the fifth day the use of a warm douche (104° F.) for five to ten minutes preceding the tub bath. The douche to be applied all over the body excepting the head and breasts; the pressure from a ¼-inch nozzle to equal 10 to 20 pounds to the square inch and preferably a fixed jet from an unvarying natural supply of thermal water.

8. Rest after the bath, preferably in the patient's bed.

*Report of the Committee on Standard Therapeutic Measures from American Electro-Therapeutic Association, Sept. 15, 1914.

9. The total number of baths to be governed by individual needs, twenty or twenty-one for average cases.

10. An "after cure" or period of relaxation from the bathing régime, under favorable climatic surroundings and under more or less medical observation, with tonic measures prominent.

11. Dietary provision and advice during treatment and for future use.

A NEW APPLICATION OF ERGOTHERAPY BY THE KELLOGG-BERGONIE METHOD IN THE TREATMENT OF OBESITY AND OTHER CHRONIC DISORDERS.

By A. J. READ, M.D.,

BATTLE CREEK, MICH.

Under the name of the Bergonie treatment a method of automatic exercise has within the last few years become deservedly popular in all parts of Europe in the treatment of obesity, and has recently awakened interest in this country. As a matter of fact the method is

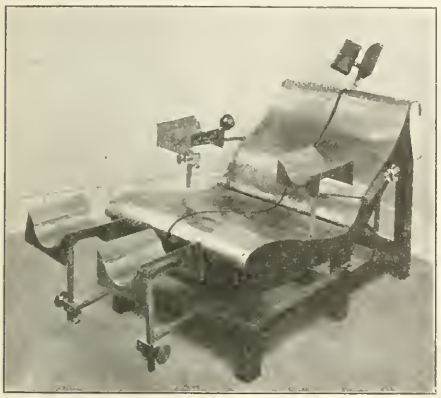

Fig. 1.—Chair for use in the application of automatic exercise.

not new. In 1886 Dr. J. H. Kellogg of the Battle Creek Sanitarium discovered the sinusoidal electric current, which he described in a paper before the American Medical Association at its Cincinnati meeting in 1888. Four years later, d'Arsonval discovered and described the current and gave it the name sinusoidal.

A most remarkable property of the sinusoidal current to which Dr. Kellogg called attention in his first paper and in later papers is its ability to evoke painless muscular contractions. d'Arsonval failed to notice this remarkable property for the reason that the currents with which he experimented were of very high frequency (10,000 to 1,000,000 per second), very high voltage (100,000 volts or more), and of very small quantity, whereas the apparatus studied by Kellogg produced a sinusoidal current having a comparatively low voltage (1500 volts), slow alternation, 4 to 60 per second, and quantity sufficient to produce a strong muscular contraction at each alternation of the current.

Kellogg early made use of this very remarkable property of the sinusoidal current as a method of automatic gymnastics. It was at once employed as a means of developing weak abdominal muscles, the weak groups of muscles in scoliosis, paretic or paralyzed muscles in cases of hemiplegia and infantile paralysis, and shortly afterward Kellogg employed it in the treatment of general and local obesity and described the method in various papers. The method of application was essentially the same as that which has been recently suggested by Bergonie.

The records of the Battle Creek Sanitarium and Hospital show that the sinusoidal current has been employed in more than 100,000 applications and in many hundreds of cases.

The method of Kellogg has several advantages over that of Bergonie. One very important advantage is that with the sinusoidal current which he has always employed very powerful muscular contractions may be induced without pain or other sensation than that due to the muscular contraction itself, whereas the faradic current employed by Bergonie produces more or less unpleasant skin sensations which requires of the patient considerable exercise of fortitude if the current is applied with a sufficient degree of intensity to secure maximum efficiency. Nevertheless, Bergonie rendered an important service in calling attention to the value of electricity as a means of inducing muscular work and the success of his method, notwithstanding its defects, has justly aroused much interest among the laity as well as among the members of the profession especially in connection with the treatment of obesity.

Obesity is a disorder of metabolism. The body fails to burn its fat, thus permitting it to accumulate, just as in diabetes the body fails to burn its sugar and allows it to be lost through the kidneys. In diabetes the problem of preventing the metabolic fault so as to enable the body to utilize its sugar is exceedingly difficult and rarely wholly successful. In obesity, however, the task is comparatively an easy one, it is only necessary to increase metabolism by increasing the activity of the muscles and to decrease the intake of fat-forming foodstuffs. During vigorous activity the rate of metabolism may be increased to eight or ten times the rate in the state of rest. The difficulty is to induce the patient to take the needed amount of exercise. A fat person becomes easily fatigued; the heart is often weak, the breath short, and not infrequently obese patients suffer from rheumatism in the knees or feet which renders much walking painful or impossible. Disease of the heart and kidneys also contraindicates prolonged or vigorous muscular exercise. Sometimes the chief obstacle is the patient's indolent disposition which may insure failure instead of success. Automatic exercise or electrical gymnastics induced by the Kellogg-Bergonie method overcomes all these objections.

The Method.—The patient lies upon a couch or reclining chair (Fig. 1) with electrodes adjusted to the groups of muscles which underlie the principal masses of surplus fat and the current is turned on. Vigorous rythmical action is produced in the several muscular groups either in alternation or simultaneously as may be desirable for the individual case. The amount of work done may be regulated by adjusting sand bags to each muscular group over the electrode so that at each contraction the muscles are compelled to lift a weight and thus do actual mechanical work (Fig. 2). It is possible to make an approximate calculation of the amount of work done; for example: A sand bag weighing 50 pounds placed over the abdominal muscles may be lifted an inch at each contraction with the muscle contracting at

the rate of twice a second or 120 times a minute. Thus a single group of muscles may in thirty minutes do 15,000 foot pounds of actual mechanical work. The large muscles of the thigh and the muscles of the arms may be made to work at the same time, increasing four fold the amount of work done and by setting the muscles of the back to work also, the total amount of work may be made sufficient to increase the total, at a very conservative estimate, to 25,000 or 30,000 foot pounds in half an hour, or say 50,000 foot pounds in an hour. These figures really represent only about one-fifth of the actual energy expended by the body since the physiologists have shown us that except under the most favorable conditions, the amount of heat produced as a by-product of muscular work represents three or four times as much energy as the mechanical work done. Taking this into consideration the real energy expended would amount to about 250,000 foot pounds.

Actual metabolism tests made by the respiration apparatus of Benedict, which measures the amount of O_2 consumed and of CO_2 produced, showed the body metabolism to be increased from 300 per cent. to 500 per cent. during a seance of automatic exercise in which the Kellogg apparatus was used.

Advantages of Automatic Exercise.—1. Perfect Adaptation. The dissipation of local fat accumulations over muscular groups which are too little exercised is more efficiently accomplished by this method than any other for the reason that the muscular work may be localized and may be increased to any degree of intensity. In general obesity there is a very uniform distribution of fat over the entire body, but even in these cases little fat accumulates about the hands or forearms or feet and lower legs, probably on account of the fact that the muscles of these parts are exercised more freely than those of other parts of the body. In the great majority of cases of obesity the fat is not equally distributed but accumulates in certain regions, especially about the abdomen and thighs and often in women about the shoulders and chest. The Kellogg-Bergonie method lends itself perfectly to both these classes of cases for the automatic exercise may be applied to all the principal groups of muscles in the body or the application may be confined to the principal masses of accumulated fat.

In the matter of adaptation to individual requirements, especially in the treatment of localized obesity, the Kellogg-Bergonie method is especially valuable since by means of it the increase of metabolic activity can be excited at the very point where it is required. A person who has an excessive accumulation of fat about the abdomen may certainly reduce fat by a large amount of muscular work, such as walking, hill-climbing, etc., but such exercises require the activity of the entire muscular system and increase the consumption of fat not only in the places where fat reduction is desired, but over the entire body. This method must involve then an enormous waste of energy, whereas with the Kellogg-Bergonie method the energy expenditure and resulting fat consumption are induced at the particular point where the reduction is needed.

Fig. 2.—Application of automatic exercise with patient lying on a couch.

2. Freedom from Fatigue. The obese person on exercise becomes very quickly fatigued, out of breath, over-heated, and can only with difficulty be induced to continue his efforts long enough to secure definite results. The majority become discouraged because the results obtained appear to be so small when compared with the efforts required. While

undergoing treatment by the Kelogg method the patient experiences no fatigue. There is no energy expended by the brain or spinal cord whatever, the patient simply lies on his couch or easy chair while his muscles are contracting vigorously under the influence of direct painless electrical stimulation.

This is a matter of very great consequence, especially in the treatment of neurasthenics who often refuse to exercise because of the distressing sensation of fatigue of the brain and nerves which follows even moderate exertion. By the use of the automatic electrical exerciser stimulus is applied directly to the muscles so that no expenditure of brain or nerve energy is required. The patient can be made to do as much muscular work as though he had walked a number of miles and without any unpleasant sense of fatigue; any exhausting effect following the application is neutralized by the tonic effects of the electrical current.

The sinusoidal current is so penetrating and so efficient in producing muscular action it passes di-

Fig. 3.—Automatic exercise apparatus (Kellogg) for the application of ergotherapy.

rectly through the skin and penetrates the body of the muscles and brings every fibre into action either gently or vigorously according to the amount of current employed. The action is absolutely automatic and independent of the patient's volition. The patient may, indeed, in the meantime occupy himself with reading or any appropriate diversion, being quite unconscious of effort or any other sensation than that of strong muscular action in the parts undergoing treatment. Not only is the patient free from fatigue and exhaustion in this treatment, but at the same time he experiences the tonic effect of the electrical currents which are constantly playing through his body. That work is being done is very soon evidenced by the fact that he experiences the sensation of increasing warmth that accompanies exercise and is soon bathed in copious perspiration. Any discomfort from this source is relieved by the attendant who wipes away the perspiration and if necessary bathes the face and applies cold cloths to the head so the patient experiences no fatigue even though an enormous amount of muscular work may be going on.

Obese patients suffering from severe cardiac disease, gout, or rheumatism are able by this method to receive the advantage of efficient muscular exercise notwithstanding their inability to engage in voluntary muscular effort to a sufficient degree to secure any reduction in weight.

3. The Kellogg-Bergonie method admits of the most perfect regulation of the dose of exercise to meet any condition or requirement. The intensity of the application may be so great as to convulse the body with the powerful muscular contractions and on the other hand it may be so modulated as to produce only the most gentle muscular action. The treatment may thus begin with a minimum dose and steadily increase in intensity from day to day as the patient's endurance increases until the maximum effects are produced.

The results under judicious management are exceedingly gratifying. The actual loss of weight which occurs during the seance is always a source of encouragement to the patient. The amount of weight lost during the half hour of an ordinary seance varies from half a pound to one pound, according to the vigor of the application. The loss of weight is rarely less than half a pound and in some cases as much as one and one-fourth pounds. It is true that this reduction of weight is largely due to the loss of water through the skin, but it must be remembered that the evaporation of the water from the skin cannot be effected without the use of heat derived from burned fat. Evaporation of a pound of water from the skin requires the burning of an ounce of fat, or its equivalent. Free perspiration is thus a sure evidence of the effectiveness of the treatment.

Under the influence of the Kellogg-Bergonie method in conjunction with proper regulation of the patient's diet together with voluntary exercise which should always accompany the treatment, if possible, weight may be reduced with any desired degree of rapidity. A reduction of half a pound a day is about the minimum rate of weight loss which should be expected. The steady loss of one pound a day or even higher rate of loss may be maintained for a short time, even for a few weeks, if care is taken to protect the patient from the evil effects of acidosis. It must always be remembered that too rapid a loss of flesh is not desirable. It is certain to result in very marked vital depression of the patient and serious disturbance of metabolism and in the most favorable cases will be soon followed by a rapid return of the flesh that has been gotten rid of at the expense of so serious an effort. What is required is that the fault in the patient's metabolism should be corrected so that with reasonable attention to regimen and the following of a few simple rules his health may be maintained on a higher level and his weight kept within reasonable limits.

Necessary Precautions in Reduction of Weight.—It is highly important to avoid such a degree of severity in the measures employed as will make necessary so rapid an attack upon the body tissues as to induce acidosis. Acidosis is always present in starvation as well as in advanced cases of diabetes and for essentially the same reason. The patient's basal metabolism is maintained at the expense of the body tissues. If the usual food intake is reduced to less than three-quarters the amount necessary to supply the energy require-

ments of the body acidosis is likely to appear. This is shown by acetone in the breath and the appearance of acetone and diacetic acid in the urine. A high ammonia content of the urine is also an indication of acidosis and is one of the most convenient methods of determining this condition. Metabolism studies by means of the respiration apparatus are on this account highly useful in connection with the treatment of cases of obesity, although it is possible to dispense with this somewhat technical method of examination by exercise of extreme care and good judgment.

It is highly important that the water intake should be increased in the reduction of body weight. It is impossible to increase fat consumption without at the same time to some degree increasing the breaking down of the nitrogenous tissues. According to Van Noorden this may be estimated as about ten per cent. of the fat consumption. It is possible by simply noting the intake of protein and determining the total nitrogen of the urine to establish a nitrogenous balance. It is desirable in all cases of weight reduction to maintain a plus balance, hence care should be taken that the protein intake is sufficient to compensate for the extra loss due to increased metabolic activity and also to provide the extra protein needed for increasing the muscular tissues that occur as a natural result of increased exercise. It must not be forgotten that the exercise required in the treatment of obesity creates an exchange of fat for muscular tissue so that the fat reduction is always more than is indicated by the scales. A portion of the fat loss is balanced by the very advantageous gain in muscular tissue.

The increase in protein metabolism naturally requires a very considerable increased intake of water to wash away the nitrogenous wastes. An extra supply of water is also required to compensate for the loss of water from the skin made necessary by the increased heat production resulting from muscular work. On an average the consumption of water should be from three to four quarts daily; the amount should be sufficient to maintain a urinary output of three or four pints or at least 1½ liters.

To aid the patient in restricting his diet and also to lessen the burden of the kidneys which are necessarily required to do much extra work, it is important to reduce the consumption of salt to about one-half of that to which the patient is accustomed to take, or even less. In some cases salt may be wholly omitted from the food with decided advantage. The lessening of the salt intake also encourages loss of weight by diminishing the water content of the body. For every ounce of salt held in solution in the fluids of the body 140 ounces of water are required to maintain the normal specific gravity of the body fluids, and a normal osmotic exchange. If by lessening the salt intake the amount of salt held in the body is diminished one ounce, the result will be a discharge of 140 ounces of water from the body or a loss of about 8 or 9 pounds of body weight for each ounce of salt.

In the use of the Kellogg-Bergonie method some little care must be exercised at the first seance to avoid too intense or prolonged applications. The failure to take this precaution may result in making the patient's muscles so sore as to discourage him. The soreness will disappear in a few days. The vigor may be rapidly increased after the first three or four days, as the muscular soreness disappears.

This method of producing automatic exercise of the entire muscular system or of individual groups is capable of rendering the very greatest service in many classes of cases besides patients suffering from obesity.

The method is particularly serviceable in the following cases.—(1) As a general application in convalescence following typhoid or other fevers. (2) After abdominal section or other surgical procedures in which the patient has necessarily been confined to the bed for some time. (3) In cases of chronic rheumatism. (4) In cases of osteoarthritis. (5) In cases of gout, sciatica and other cases in which the patient is unable to walk. (6) In cases of rest cure. (7) In a great number of cases of enteroptosis or viceroptosis which is common in women on account of the weakness of the abdominal muscles. By this method the abdominal muscles may be rapidly strengthened and enabled to hold the vicera in place and to maintain the intra abdominal pressure necessary for good blood circulation. (8) In cases of paralysis and cases of deficient muscular development as in cases of scoliosis.

This list might be very greatly extended for, as a matter of fact, there are few cases of chronic disease in which the Kellogg-Bergonie method may not be employed, not as a substitute for exercise, but as a highly useful means of supplementing other forms of exercise.

A CASE OF DIPHTHERITIC TRACHEOBRONCHIAL CASTS IN A WOMAN 50 YEARS OF AGE.

By A. LEVINSON, M.D.,
CHICAGO.

TRACHEAL membranes are not uncommon in diphtheria, in fact most cases of laryngeal diphtheria present a tracheal membrane post mortem or ante mortem (when coughed up or removed by the introduction of an intubation tube.) Tracheal membranes, however, are of most frequent occurrence in children between the ages of 1 and 5, this period supplying the greatest number of laryngeal diphtheria. (See Schick's Table in the *Zeitschrift für die gesammte experimentelle Medizin*, Band IV, Heft 2.) With advancing age laryngeal diphtheria becomes less frequent. This may be due to the fact that the older child or adult calls attention to the oncoming disease when it is still located on the tonsils and thus prevents its further progress, or the shape of the young child's larynx, which is so much narrower than that of the maturer person may render it more susceptible to the formation of a membrane. We thus see very few cases of laryngeal diphtheria in adults, especially in old age.

While serving as resident physician at the Chicago Contagious Hospital, I had occasion to treat a case of diphtheria, in a woman of 50, in which the disease extended over the larynx, bronchi, and bronchioli. Besides its infrequency I found the case interesting for the rapidity with which new membranes formed over the trachea and bronchi, and for the formation of the casts which the patient coughed up. The history of the case follows:

Mrs. H. Y., aged 50 years, had diphtheria in infancy. A scar was still to be seen on her neck from the blisters applied to it, which was a very popular treatment for diphtheria in those days. She had also had scarlet fever, measles, chickenpox, and whooping-cough in her childhood. With the exception of these diseases, her health was good until two years ago, which marked the beginning of her menopause, when she began to feel pain in her abdomen. She had three ovarian cysts re-

moved, recovering from the effect completely in three months.

On August 28, 1911, patient had a sore throat and a temperature of 99.4 , but she paid little attention to either. On the 29th she had chills and her temperature rose to 100.2 . She complained of severe headache. She called in a Christian Scientist, who had been treating her very frequently for nervousness. The Christian Scientist made light of her condition, and assured her prayer, for which she was to pay $2 per visit, would cure her. On August 31 her condition grew worse. Her temperature rose to 103 , and the family becoming alarmed called a physician, who swabbed her throat with nitrate of silver, and took a culture which he forwarded to the municipal laboratory. The day following, the culture having been found positive, the physician administered 10,000 units of antitoxin and sent the patient to the Chicago Contagious Hospital. On the way to the hospital, the patient claimed that she had coughed up a big cast, a fact, however, which was not verified by the ambulance surgeon.

Upon arrival at the hospital at 5:30 P. M. patient showed a temperature of 103 , pulse 108, respiration 24. On examination a membrane was seen over the tonsils, fauces, extending way down to the larynx. The glands on both sides of the neck were swollen and tender to the touch. A scar was noticed on the neck, as previously mentioned. Heart was normal in outline; heart tones weaker than normal. Dry râles were heard all over thorax; otherwise negative.

A culture was taken from throat which, morning after, presented a thick membrane-like growth consisting of Klebs-Loeffler bacilli.

Ten thousand units of antitoxin were injected into patient at 10 P. M. in order to allow time for the first dose of antitoxin to take effect; 1 grain of calomel was administered followed by 2 ounces of sulphate of magnesia. Hot compresses were applied to the neck and hot water was given to the patient very frequently. She was very restless all night, but her temperature gradually subsided so that at 8 A. M. the next morning (September 2) it fell to 98.8° and the pulse to 84. Respiration, however, still continued at 26 per minute and was very labored. Patient started coughing in the early morning and at 11:30 after a paroxysm of eight minutes she coughed up a cast which had the impressions of the thyroid cartilage, all the tracheal rings,

Fig. 1.—Diphtheritic cast coughed up by woman 50 years of age, extending over larynx, trachea, bronchi and bronchioli. Unfortunately the nurse put it in alcohol, which coagulated the membrane and caused it to fall to pieces, leaving only the part that lay over the tracheal rings.

right and left bronchii and bronchioli on the left side (Fig. 1). After this she was entirely relieved and rested comfortably the rest of the day. We administered 10,000 units of antitoxin on that day and 10,000 more the next day, which she spent comfortably. At night (September 3) patient again became restless after having coughing spells every few minutes, and at 10:30 the next day she coughed up a membrane similar to the previous one except for its size, this one being about ¾ inch longer (Fig. 2). The tempera-

Fig. 2.—Diphtheritic cast, second (according to patient third) to be coughed up inside of 24 hours. Cast shows the markings of the thyroid cartilage, tracheal rings, bronchi and some bronchioli.

ture fell to 99.8° and did not rise any more. Ten thousand more units were given on that day, making a total amount of 95,000 units of antitoxin. Patient felt very well after she coughed up the last membrane except for the weakness she experienced. The cultures taken from her throat showed involuted bacilli and on the fourth day the culture was entirely negative. The patient was very anxious to get out of bed, though warned repeatedly that the slightest exertion on her part might result in an acute dilatation of the heart. This really occurred on September 19, when she got out of bed and walked around in the ward. She was put back to bed and stimulated by strychnine sulphate and camphor, but her heart did not return to normal, and on September 20 she succumbed to acute dilatation.

30 N. Michigan Boulevard.

The Communicability and Control of Whooping-Cough.—E. Feer calculates the incubating period in this disease as from seven to twelve days. He finds that it is infectious chiefly during the catarrhal stage at a time when the diagnosis cannot yet be established. There is a psychic factor which comes into play in the control of the attacks. Replacing an anxious mother by a tactful nurse frequently has a favorable influence in the entire course of the disease.—*Medizinische Klinik.*

A CASE OF A ROUND CELL SARCOMA OF THE MENINGES OF THE BRAIN.

By G. A. RUECK, M.D.,

NEW YORK.

(From the Department of Pathology, Fordham University Medical School, New York City.)

BRAIN tumors are rare as compared with other diseases of the central nervous system and for that reason the following case is reported, although its history is incomplete.

Anna G., 24 years old, Irish, single, domestic, in the United States 8 months, was admitted to St. Francis Hospital August 11, 1911, with the diagnosis of meningitis. The patient related that she had received a blow on the right side of the back of her head some time ago. Her present illness started three weeks prior to the admission to the hospital with a dull frontal headache, neusea, and vomiting. These symptoms continued until her death. She was conscious when she entered the hospital and could walk and read. The temperature ranged from 99° to 103° F. The patient died within 24 hours after her admission to the hospital. (I reported this case to the Bronx Medical Association, March 28, 1912.)

With permission of the coroner's physician, Dr. Riegelman, I performed the autopsy August 12, 1911.

Photograph of brain and tumor (taken by James Coughlan, M.D., surgical intern at St. Francis Hospital). The left half of the brain is somewhat distorted by an improper position in the jar during the process of hardening. The dotted line points to the tumor.

Autopsy: A middle-sized, fairly nourished Irish girl. The viscera were negative. The hymen was intact.

Brain and Meninges: The dura was normal. The brain convolutions were somewhat flattened and the fissures comparatively narrow due to internal hydrocephalus produced by the pressure of a tumor. The tumor was situated between the left lobe of the cerebellum and the left occipital lobe of the cerebrum. It was visible posteriorly where it was not covered by the overhanging left occipital lobe. Judging from this visible portion alone the tumor might have been taken for a spherical structure. Anteriorly the tumor reached to the pons. The left lobe of the cerebellum was slightly pushed over to the right and its upper surface on which the tumor rested was smooth and depressed. There was also a smooth depression made by the tumor on the inferior surface of the left occipital lobe of the cerebrum. Depressions made by the tumor on the pons and cranial nerves were not noticed. Except for a reddish hue the tumor was of the same color as the brain. It had nearly the shape of a hen's egg, weighed 7 grams and was 40 mm. long, 25 mm. wide and 20 mm. thick. It was not adherent to the brain substance, was of a denser consistency than the brain and contained small yellowish granules which did not grate on section.

Microscopic Examination.—The cells making up the chief bulk of the tumor had an alveolar arrangement. They were closely packed and of the size of large mononuclear leucocytes; some of them were of the size of lymphocytes. Most of them were round, some elliptical and some polyhedral. They had little cytoplasm and large, deeply staining, granular nuclei. Some of them had a deeply staining nucleolus. These round cells of the tumor must have originated from the walls of the blood vessels and, being closely packed in an alveolar arrangement they must have been en masse the yellowish granules seen macroscopically. Trabeculæ forming a reticular framework traversed the tumor. In some places they were narrow strands, in others they were as wide as three diameters of the microscopic field of the low power objective. The trabeculæ were made up of connective tissue cells of the embryonic type. The nuclei of these cells were large and elliptical; a few were sausage-shaped or polyhedral. The cytoplasm cell processes and cell cement took a lavender color with an eosin-hematoxylin stain; the nuclei stained somewhat darker. This framework of the tumor originated from the sheaths of connective tissue surrounding the blood vessels of the pia. It carried comparatively few blood vessels. No blood vessels were seen in the "alveoli" of the tumor. There was no free hemorrhage in any part of the tumor. Each section showed many small and a few large areas of necrosis.

The pia surrounded the tumor as a thin capsule. There was no infiltration with tumor cells of the neighboring brain substance. (Brain and tumor were given to the museum of Fordham University Medical School and have the number 721.)

According to the above description the tumor was a round cell sarcoma. This case would have been excellent for brain surgery.

1070 TIFFANY STREET.

CARCINOMA IN THE YOUNG.

REPORT OF CASES.

By ROYALE H. FOWLER, M.D.,

BROOKLYN, N. Y.

CASE I—*Carcinoma of the Rectum, Diffuse Peritonitis.* P. W., age 15, was admitted to St. Luke's Hospital, New York City, service of Dr. Robert Abbe, in November, 1907. The chief complaints were pain in the rectum and abdomen. Patient had been in good health until somewhat less than one year ago when he lost his appetite and had cramp-like pain in the abdomen. Six weeks later the stools became tinged with blood. The bowels had previously been constipated. He visited several hospitals and was later sent to the country. No relief was obtained and finally examination under ether revealed an inoperable condition. There had been a marked loss of weight. No vomiting, cough, urinary, or other symptoms. His condition grew worse and the boy was admitted to St. Luke's Hospital in a pitiful condition suffering in addition from multiple bed sores and a pararectal abscess. The boy's mother died of cancer of the stomach.

Clinical findings. Blood examination revealed on admission a leucocytosis of 19,400, Polys 83, Lymph. 17. Temperature varied from 98 to 102, the pulse from 120 to 144. Respiration from 16 to 28. Stools became involuntary. The patient was beyond help and died. The autopsy performed by Dr. Hans Zinsser is herewith appended. The body is that of a very much emaciated boy. No signs of external injury. There is extreme edema of both lower extremities below the knees. Both feet are enormously swollen. Pupils equal and mid wide. There are numerous bed sores at various bony points. Above the anus and around it there is some superficial ulceration of the skin and on the left buttock, one-half inch from the anus, there is the opening of a sinus which leads into the ischiorectal region. It exudes pus. Upon inserting the finger into the rectum a hard ulcerated mass is felt 3 x 4 cm., about 6 cm. from the anal opening. External genitals normal. Superficial axillary and cervical lymph nodes slightly enlarged. The inguinal are three times the normal size.

Thorax: Lungs show old tuberculosis scars at both apices, organs edematous, slightly congested at base. Bronchial lymph nodes slightly enlarged. Left bronchi exude pus. Thymic remains small, no enlarged mediastinal glands. Heart wall of the left ventricle is thin.

Considerable atheroma just above aortic valves and of the aortic arch.

Adbomen: Thick grumous pus upon opening peritoneum. Contained no feces. Liver, congested, moderate perihepatitis. Slight amyloid and fatty degeneration. Kidneys, embedded in soft purulent adhesions in which capsules are involved. Ureters free. Pancreas, suprarenals, gall-bladder, and ducts normal. Intestines, large and small, are matted together by fibrinous and purulent adhesions, wall thin, serosa lustreless and covered with fibrin. Mucosa intensely congested. Mesenteric lymph nodes slightly enlarged. Rectum is embedded in a thick mass of new growth. It is firmly adherent to the walls of the pelvis. This mass has infiltrated and displaced muscles of the pelvis and has grown through the sacrosciatic foramen. The entire region is burrowed with intercommunicating sinuses which are filled with pus. The wall of the rectum is so infiltrated and thickened that slight tension tears it. No perforation of the rectum. Appendix normal.

Microscopic diagnosis, adenocarcinoma of the rectum.

This case is of interest on account of the extreme youth of the patient, the rapidity of the growth, and because of the failure of early diagnosis.

Carcinoma is rarely observed in such young subjects. When it occurs in the bowel it is most frequently encountered in the large intestine, the sigmoid usually being credited with the site of predilection.

Twenty-one cases of carcinoma of the large bowel occurring in young persons have recently been reported by French observers. Of these nine were in the cecum and twelve in the sigmoid. As regards age, two cases were under ten years of age, eleven were under twenty, and seven were under twenty-five. Thirteen cases occurred in males. In this series the disease progressed rapidly to a fatal issue. In all but two cases, seven or eight months elapsed between the first signs of trouble and death. In these, two and four years elapsed respectively.

The first symptoms to attract attention are usually: (1) local pain, (2) melena, (3) diarrhea. Four cases had progressed to advanced stages. In three cases sudden complete ileus occurred, in one ascites. In five cases the growth was removed. Three were said to be cures "for the time being."

Case II.—*Mammary Carcinoma, Recurrence, and Metastasis.* Bessie M., Russian Hebrew, aged 20, was admitted to the Kings County Hospital, service of Dr. J. Bion Bogart, on Sept. 17, 1914. The patient first noticed a growth in the breast when 17½ years of age. She was married at 19 and immediately became pregnant. The growth was observed to increase rapidly in size at this time. At the Mount Sinai Hospital, in February, 1914, pregnancy was terminated and radical amputation of the right breast performed by Dr. Berg. Upon microscopic examination the tumor was diagnosed scirrhus carcinoma. Multiple incisions were made subsequently in the axillary flap for drainage. Following operation she felt well until nine weeks prior to admission to the Kings County Hospital, when she first noticed pain in the right knee, which radiated to the thigh and hip. Pain was also experienced in the right shoulder. This was constant with consequent impairment of function. It was worse at night. The pain in the shoulder was more severe. She had not rested well at night since onset. There was loss of appetite, marked loss of weight and weakness. The stomach was "easily upset" and she vomited occasionally. Constipation present. Physical examination on admission. The patient is a young Jewish girl of medium frame. Skin and mucous membranes of fairly good color. Head: Pupils equal, react to light and accommodation; tongue, fairly clean, teeth good.

Neck: Posterior cervical glands palpable. Right supraclavicular space more prominent than left.

Thorax: On the right side of the chest there is a scar of a radical amputation of breast, which is much thickened throughout its entire extent. Below and external to the main scar there are numerous smaller ones about one-half inch in length. These are also hypertrophied. High up in the axilla there is a small reddened papule suggesting metastatic malignant disease. In the axillary line there is a similar reddened papule in a small hypertrophied scar.

Left Breast: There is a hard diffuse infiltrating swelling at junction of third rib with sternum (upper inner quadrant). It is somewhat moveable and of indefinite dimensions, not tender. Overlying skin uninvolved. There is a scar in this situation which feels nodular. Palpation of the axilla on this side shows moderately enlarged glands along the upper border of the pectoralis major.

Heart, action regular, fairly strong; displaced or enlarged slightly downward; no murmurs heard. Lungs, negative.

Abdomen: Liver and spleen apparently not enlarged. No masses or tenderness. There seems to be a slight resistance just below and to the right of the umbilicus.

Genitalia: External, normal. Cervix, small, stellate scar, in axis of vagina. No adnexal masses felt. Body of uterus retroverted. Not enlarged and drawn over to patient's right.

Extremities, negative.

Reflexes, brisk. Babinski, negative. Clonus, negative. Sensation, good.

Mentality, good.

October 23, 1914, patient seems somewhat improved, appears much brighter, and complains less of pain. Wassermann, negative. Gonococcus fixation, negative. Urine, routine examination negative. Gastric contents: Total acidity, 15; free hydrochloric acid, 5; organic acid and salts, 5.

On October 29, 1914, a small papule was removed under novocain anesthesia and sent to the laboratory. An area of scar tissue was also removed for diagnosis.

Pathological report by Dr. Terry: A diamond shaped piece of skin and subcutaneous tissue. In the center of the piece of skin the epidermis is thin and slightly reddened. Beneath this area the subcutaneous tissue is found to be firm. On examination with a hand lens this tissue is found to contain interlacing white silvery strands which reach the epidermis. The relation of strands to epidermis cannot be made out, although the epidermis does not appear thickened over the strands.

Frozen section. Microscopical examination. The stratified squamous epithelium of the skin shows some slight irregularity in its growth, but none of the downward growing projections invade the underlying tissues to any great extent. Beneath the epithelium there is an increase in the connective tissue and in the crevices of this stroma are seen dark staining cells often arranged in long columns. These columns of cells anastomose and suggest epithelium.

Rapid paraffine section. Microscopic examination. The staining of the columns of cells is better and their relation to the fibrous stroma is better seen than in frozen section.

Diagnosis: Scirrhus carcinoma.

The radiographs of the right shoulder and thorax showed hazy areas of infiltration in the head of the humerus and left side of the chest very suggestive of metastatic carcinoma.

The patient was discharged at her request October 9, and was readmitted November 14, 1914, complaining of headache, vomiting, pain in the chest, and hoarseness. Pain was severe and situated on the left side of the thorax. The left breast showed a large crusted ulcer. The pulse was rapid, irregular, and of poor quality and required active stimulation. The respirations were rapid and shallow. The patient was in very poor condition. Temperature 98°, pulse 120, respirations 28. She became progressively weaker and expired November 16.

To recapitulate: When 17½ years of age this girl first observed a swelling in the left breast. This grew rapidly following pregnancy which occurred one and one-half years later. At the sixth month pregnancy was terminated. Following this when 19 years of age she was subjected to radical amputation of the right breast by Dr. Berg at the Mount Sinai Hospital.

Our studies at the Kings County Hospital six months later revealed recurrences in the main scar as well as in the multiple scars resulting from incisions for purposes of draining the axillary flap. The latter are not to be regarded as instances of implantation carcinoma but true recurrences. (The

incisions were made subsequent to operation.) There was invasion of the opposite breast and enlargement of the axillary lymphatic glands upon that side as well as invasion of the left lung and right humerus. These are to be regarded as evidences of metastasis. She died in less than nine months following operation or in less than eighteen months since the tumor was first observed.

We have again in this patient a case of great interest because of the youth of the subject, and because of the rapid progress to the fatal termination and wide dissemination of the disease.

In this connection, a case of mammary cancer occurring in a young boy is of interest, reported by Robert C. Bryan of Richmond, Va.

A. C., aged 14 years, 8 months, operated on February 6, 1913. In August, six months before operation, the boy, while playing golf, was struck a violent blow on the right breast in the region of the nipple by a golf ball in flight, which made him quite sore for several days. He soon got over the soreness, paid no further attention to it, but six months later, in January, while bathing, noticed a little lump under and very close to the right nipple. It was not painful, but recalling the blow he received, his family decided to have the tumor investigated. On examination the boy was found to be an exceedingly well developed specimen, 5 feet 2 inches in height, weighing 116 pounds, erect in figure and enjoying the best of health. The family history is negative throughout; heart and lungs negative. Uranalysis negative, and the blood count of no particular interest. A small, round, hard tumor, about the size of the smallest cherry stone, was found in the lower right quadrant about one-eighth of an inch from the nipple, freely movable under the skin and on the underlying fascia. There was no retraction of the right nipple or dimpling. The skin over the tumor showed nothing unusual and the most careful investigation of the glands in the axilla and about the clavicle and the inguinal region gave no evidence of their enlargement. In the last week the growth had been handled and palpated considerably and consequently was a little tender.

Under general anesthesia a semicircular incision was made under the breast, the flap dissected back, the tumor and surrounding fascia were removed down to the pectoral muscle, and the wound brought together without drainage, the patient leaving the hospital in three days. A report by Dr. S. B. Moon, pathologist to Grace Hospital, states that "the specimen, 1014, is adenofibroma with distinct scirrhous carcinoma in scattered areas of rather active cell proliferation."

The youngest case which Bryan was able to find in the literature was reported by Bloodgett.

His attention was called to a boy, 12 years of age, who was born of healthy parents and in whom no suspicion of malignant heredity could be found. Up to the age of twelve years this boy presented no indication of glandular or other disease. Soon after this time swelling was noticed in the left breast, beneath and attached to the nipple, which was slightly reddened and harder than its fellow of the opposite side. The growth on microscopic examination presented the typical structure of carcinoma, and had invaded all visible glandular tissue of the breast. The wound healed by first intention and there was no indication of recurrence or metastasis five years after operation.

Carcinoma has appeared in youth in almost all the favorite sites of the adult.

Carcinoma of the prostate is reported by Gardner and Commins in an American machinist apprentice, age 17, admitted to hospital October 2, 1911. His last illness began seven weeks before with colicky pains in the left side of the abdomen accompanied by vomiting. The pains radiated to the left testicle. There was no hematuria. Incontinence of urine. Three weeks previously the pain had shifted to the right side of the lower abdomen and radiated to the right testicle. He had lost much weight. The uranalysis was: Clear; sp. gr. 1018; acid; no sugar nor albumin; no casts. Death occurred January 12, 1912. Permission for a partial autopsy only was granted, so an examination of the thoracic organs and central nervous system could not be made. The clinical diagnosis was sarcoma of the prostate, the pathological, (1) carcinoma of the prostate and retroperitoneal lymph-nodes; (2) chronic interstitial splenitis and hemosiderosis; (3) passive congestion of the liver; (4) chronic parenchymatous nephritis; (5) hydronephrosis and hydroureter; (6) chronic interstitial pancreatitis.

Instances of carcinoma in other situations in youth are not lacking. The writer recalls a case of primary carcinoma of the liver in the person of a young woman of twenty-two, who was operated upon by the late George Ryerson Fowler at the Methodist Episcopal Hospital.

Smithies has recently undertaken a study of sixteen cases of gastric cancer in patients under thirty-one years of age.

Reports upon gastric cancer in the first three decades may be of interest here. According to Smithies, six cases have been recorded under the age of ten years (dubious). In but eight of thirteen cases in the second decade were there reliable pathological reports. Thirteen cases have been collected in the third decade, however, with but few pathological findings.

The proportion of gastric cancer in the young, according to 150 cases analyzed by Osler and McCrea, was 4 per cent. In larger series, the percentage has varied, thus in 2,038 instances tabulated by Welch the ratio was 2.8 per cent. In Smithies' group of 721 cases, from the Mayo Clinic and Augustana Hospital, the percentage was 2.2.

AN APPLIANCE FOR PRODUCING SIMULTANEOUS SUCTION AND PRESSURE FOR USE IN TONSIL AND ADENOID OPERATIONS.

By J. G. L. BORGMEYER, M.D.,
Ophthalmic, Aural, and Laryngological Surgeon, Bayonne Hospital,
and
CHARLES J. LARKEY, M.D.,
Bayonne, N. J.
Anesthetist, Bayonne Hospital.

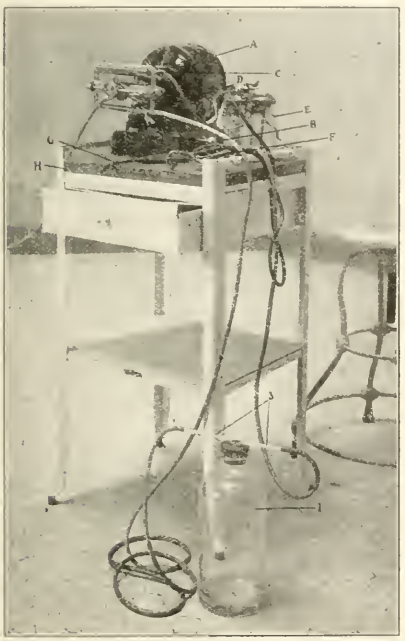
In operating for the removal of tonsils and adenoids the proper mode and means of administering the anesthetic and the keeping of the field of operation free from blood has been a question. Having struggled along for a long time in this line of work, adding this and discarding that, we have finally adopted the apparatus shown in cut.

We are able, owing to the strong suction, constant and even, to keep the operative field absolutely clean continually, and the patient fully under the anesthetic.

Our method of procedure is as follows: We first anesthetize the patient by the open drop method, using a 25 per cent. solution of the oil of bitter orange in alcohol to mask the odor of the ether, which we then use in the ordinary way. After the

patient is fully anesthetized we substitute for the open mask a mouth gag, which has vapor tubes soldered to it. This gag is connected by means of a rubber tube to a three bottle Gwathmey inhaler, which in turn is connected also by means of another rubber tube to the pressure cylinder of our apparatus.

The main feature that we sought in our apparatus was a simple means of driving a constant, even, and easily regulated stream of vapor, and at the same time with the same motive power, to have a machine that would create suction constant and powerful. This is accomplished by attaching an aspiration bottle, by means of rubber tubing, to the cylinder of the pump, as shown in the cut, and a metal suction tube is attached to the bottle also by means of rubber tubing. Of course, the bottle contains a rubber cork with metal tubes inserted in



Suction and Pressure Apparatus. A, motor; B, rheostat; C, pressure cylinder; D, suction cylinder; E, Gwathmey three-bottle apparatus; F, mouth gag with vapor tubes; G, metal suction tube; H, grooved wooden slab; I, aspirating bottle; J, metal tubing.

two openings connected to the rubber tubing. We use the metal tube instead of glass, as the glass is often broken.

We have discarded entirely the rubber nose tubes as used by a great many surgeons for suction, because we have found them unnecessary and inefficient, and use instead the metal mouth tube, which, if properly handled, is never in the operator's way and is absolutely efficient, as every move of the operator can be followed and the field of operation is always kept clean.

Apparatus.—We use a one-eighth horsepower motor of the R. G. S. type, mounted on a wooden slab that is grooved to receive the base of the motor to prevent creeping while in action. This slab also contains grooves for the Gwathmey apparatus to prevent the bottles from being tipped over. This slab is placed on the anesthetist's table. To the motor we attach a double cylinder pump for suction and pressure. One cylinder pumps the air through the Gwathmey apparatus for anesthesia, while the other produces suction, thereby drawing the blood and mucous from the field of operation to the aspirating bottle. The motor has a rheostat attachment to regulate the rapidity and force of its action.

We have been using the above apparatus for the past eighteen months, both in private and hospital practice, and have found it very satisfactory.

Medicolegal Notes.

Defense of Malpractice Suits by a Medical Society.—On October 15, 1910, an action to recover $25,000 damages for malpractice, alleged to have occurred August 5, 1909, was commenced against the plaintiff, who immediately presented the summons and complaint to the secretary of his State Society and demanded that it proceed in accordance with its by-laws and assume the defense. This officer declined to take the papers, declaring that, as the alleged malpractice occurred prior to the adoption of the by-laws in which the Society assumed the duty of defending its members the association was not thereunder required to defend the action. The Society's legal adviser also declined to take the defense. The malpractice action was dismissed, and another, based on the same claim for the same amount of damages, was commenced. In defense of this the plaintiff incurred the expense sued for. The defendant, however, had no notice of the second action until after its determination.

It was held that the by-laws were applicable to claims arising prior to their adoption, the only exception therein relating to causes of action antedating membership, and none other could be implied. Subject to the specified conditions the by-laws imposed upon the association a legal obligation to defend suits against members. The plaintiff, having made due application to the defendant's secretary for assistance, was not required to apply to its council; nor was it necessary to give notice of the second action after the defendant's refusal to defend the first. The burden of pleading and proving that a demand for aid thereunder involved a claim upon which the plaintiff was not entitled to aid was upon the association.—Penhall v. Minnesota State Medical Association, Minnesota Supreme Court, 148 N. W. 472.

Authority of General Manager to Bind Company for Medical Services to Employees.—A corporation engaged in the publication of a daily newspaper was sued by a practicing physician and surgeon for attendance on an employee of the former, who, while engaged in the line of his duty in the pressroom, had his hand crushed. The injury was received at a late hour at night when all officers, including the general manager and the assistant general manager, were absent. The night editor, the highest agent of the company on duty, upon being notified of the employee's condition, called the plaintiff over the telephone to attend the injured man. He responded and gave first aid treatment, respecting compensation for which no question was made, the company having admitted liability therefor. The contest was over that part of the bill which represented subsequent visits to the employee at a hospital to which he was removed and office treatment. It was held that there could be no recovery of this, under the rule (not invariably followed by the courts) that even the general manager of a commercial corporation has no authority or power implied from his official position to commit his company to the payment of ordinary attendance (as contradistinguished from emergency attendance) by a physician or surgeon on an employee of the corporation injured while in the line of duty.—Journal and Tribune Co. v. Loves, Tennessee Supreme Court, 169 S. W. 760.

Liability of Board of Medical Examiners.—The Supreme Court of Colorado holds that the members of the State board of medical examiners are answerable for their official conduct to the chief executive of the State, and their civil or criminal liability is a question for judicial determination, upon a full and complete hearing in the light of the law and the facts appearing.—Kenehan v. Barber (Col.), 143 Pac. 370.

MEDICAL RECORD.

CONTRADICTORY FINDINGS IN THE WASSERMANN TEST.

DOUBT has been thrown, more than once, on the accuracy of the findings of the Wassermann test. This element of doubt, however, does not mean to say that the test is not a reliable index of the state of the blood, but it rather infers that the method is not invariably carried out with the scientific care that is necessary. Dr. Abraham L. Wolbarst of New York has pointed out in a paper published in the *Interstate Medical Journal* for February, 1915, that the test is not always satisfactory, and has called attention to some of the defects of the method. Wolbarst's personal experience in the study of such contradictions has been that in the presence of active lues, the Wassermann reaction is apt to be uniform in the hands of several serologists; in latent lues, however, or in cases which have been under treatment for some time, the contradictions are most frequently found. In the paper here discussed the views expressed are based on a careful study of 134 private cases. The conditions under which this study was made adhered as closely as possible to the conditions under which the average practitioner obtains his Wassermann tests. The results of the findings of these cases in three laboratories are tabulated and analyzed, and it is shown that there were many contradictions.

The conclusions arrived at by Wolbarst were as follows: (1) Three serologists working independently, tested sera simultaneously in 85 cases; they agreed in 42 per cent., differed more or less in 19 per cent., and there were gross contradictions in 39 per cent. of the cases. Two serologists working independently and simultaneously, examined sera in 49 cases; they agreed in 65 per cent., differed in 23 per cent., and there were gross contradictions in 12 per cent. of the cases. (2) The Wassermann reaction is dependent for its result on the skill and knowledge of the serologist. (3) The results of the test depend in a great measure on the absolutely perfect standardization of the reagents used; these are subject to variation in the hands of different serologists. (4) As a result of these differences, diversity in results is not infrequent. (5) It is a gross error to accept the findings of one serologist as conclusive; his work should be checked up by one or more equally competent workers. (6) If more than two competent serologists report on a given serum, the majority opinion may be accepted as fairly conclusive; frequent re-examinations are always of advantage to the patient. (7) All mention of results of the Wassermann test, in the literature or elsewhere, should be accompanied by the name of the serologist who made the test, in order that the measure of accuracy and skill employed may be estimated. (8) The serologist should be selected with the same care and caution that are exercised in the selection of a consultant or expert in any other branch of medical science. (9) Reagents should be prepared and distributed at a central station; all workers should adopt a uniform, recognized method which has been found reliable; meanwhile, Wassermann reports should be accompanied by the name of the individual worker who made the test, together with a brief statement showing the method, apparatus, and reagents used. In this way only can be determined the degree of confidence to be placed in the reports handed in by serologists.

Undoubtedly, there have been and are contradictions in the findings of the Wassermann test, but this fact must not be allowed to weigh against the value of the test, which has, on the whole, absolutely proved its worth. Yet, it is open to error in manipulation, and the very greatest care should be exercised with regard to the accuracy of the technique. The blood should be fresh, and a uniform, recognized standard of doing the method should be adopted, and, as Wolbarst suggests, reagents should be prepared and distributed at a central station, perhaps by the Board of Health. Also more than one serologist should do the test, and due attention should be paid to the clinical history of the case.

EXTRAVASCULAR THROMBOSIS.

THAT all of the bodily cells contain a ferment that activates the formation of fibrin has been generally recognized ever since the experiments reported by Spangaro and Arthus in 1900. The subject of the rôle played by the blood platelets in the process of clotting was veiled in obscurity until Ribbert's announcement in 1914 that following a vascular lesion there are formed in the neighborhood of the latter trabeculae of blood platelets exactly similar to those that develop during the process of thrombosis within the lumen of a blood vessel. The prime element in the process of thrombosis that occurs in the tissue spaces in the neighborhood of a wounded blood vessel therefore appears to be an agglutination of the blood platelets.

Further investigations on this subject have been carried out by Silvano Menghetti (*Lo Sperimentale*, January 20, 1915) whose conclusions are largely in agreement with those advanced by Ribbert. He finds that the hemorrhagic foci formed outside of the wall of an artery or vein as the result of an injury of this wall, there develop sooner or later typical thrombi not unlike those that are formed within the blood vessels. These thrombi appear within one to three minutes after the infliction of the injury. The process of their formation begins with an agglutination of the blood

platelets to which there is added not infrequently an agglutination of the leucocytes. This process is closely related to the presence in the extravasated blood of remnants of tissue which are deposited in the neighborhood of the injured blood vessel. The cause of the clumping of the blood platelets is partly of a chemical nature, being bound up with the alterations in the endothelium of the blood and lymphatic capillaries; and partly of a mechanical nature, for the physical character of the cellular surface with which the blood is normally in contact has an important rôle in preventing the formation of thrombi. Adipose as well as muscle and connective tissue possesses conspicuously the property of being the seat of extravascular thrombi. Neither the slowing in the blood current nor other mechanical alterations such as the development of vortices, etc., are essential in the causation of the thrombi of platelets or of the secondary thrombi that consist in the deposition of fibrin. The fact that fatty tissue favors the formation of thrombi may be turned to practical advantage in the use of transplants of fat as a means of effecting hemostasis.

CARE OF THE FEEBLEMINDED.

IT is quite patent that the whole scheme of caring for the feebleminded is in as chaotic a state to-day as was the provision for the insane before the advent of State care in 1889. To set this whole matter right, it is obvious to the careful student of the subject that a broad and comprehensive policy needs to be outlined for meeting the problem of feeblemindedness in this country.

A unique opportunity is now at hand for New York State that has done so well in its pattern of State care for the insane, to develop and put into practice a proper regime for the care and protection of the feebleminded. A general plan of approach to the whole subject has been excellently outlined by a special committee of the New York Psychiatrical Society, as published in the MEDICAL RECORD of April 17. This carefully thought-out plan signally appeals to us, and the next step would seem to be to ask that in the coming revision of the New York State constitution there be placed among its articles a provision for a State mental deficiency Commission, and that the same should then be left to the Legislature to carry into execution.

Obviously the first thing to do, once such a commission is provided for in the constitution and properly established by legislative enactment, will be to place on the board members of the different groups of societies most widely interested in the subject. When this is done it may then be possible for such a fully representative commission to formulate a coherent and all-embracing plan to meet the present needs of a State-wide policy for handling the question of feeblemindedness. Then, and not until then, will it be possible for us to get away from a purely speculative program as to what should actually be done. Such a commission would have as a guide the British Royal Commission, whose epoch-making report, carried to its finality by Parliamentary enactments, has solved the problem of the progressive governmental control of the whole question. Until such a commission is established and proper surveys made, it behooves us all to contribute so far as possible our aid and support to the essential tenets laid down in this preliminary study, which we have been pleased to publish, and to the support of which we would earnestly urge the medical profession.

THE MEDICAL PROFESSION AND THE SINGLE STANDARD.

PROFESSOR Münsterberg in his "Psychology and Social Sanity," published in 1914, shows that he is very much behind the times regarding the opinion on sex morality among reputable physicians. He writes: "The hope that man will become sexually abstinent outside of married life is fantastic, and the book of history ought not to have been written in vain. Any counting on this imaginary overcoming of selfish desire for sexual satisfaction decreases the chances of real hygienic reform. It would even be an inexcusable hypocrisy of the medical profession if, with its consent, one group of specialists behave as if sexual abstinence were the bodily ideal, while thousands of no less conscientious physicians in the world, especially those concerned with nervous diseases, feel again and again obliged to advise sexual intercourse for their patients. We know to-day, even much better than ten years ago, how many serious disturbances result from the suppression of normal sexual life."

Professor Münsterberg is mistaken about the prevailing opinion of the medical profession in this country, and as to that of the medical profession in Europe we can quote Mr. Flexner who made a special study of prostitution over there. In "Regulation of Prostitution in Europe" (*Social Hygiene* December, 1914) he says: "Time was when European medical men favored this view, and practice conformed without opposition to this demoralizing theory. Now, for the most part, they take precisely the opposite view. They regard masculine continence as feasible and wholesome; sexual irregularity is in consequence less generally condoned and is probably beginning to diminish."

Most scientists and physiologists, who have given this subject thought, have expressed themselves unequivocally that there is no absolute necessity in the physiological structure of humanity for sexual intercourse. Moreover no enlightened physician, even aside from his natural human interest, could advise promiscuous sexual intercourse in face of the facts that such an overwhelming proportion of the women found in commercial vice are infected with venereal disease.

NEWER BACTERIA OF THE COLON TYPHOID GROUP.

BETWEEN the years 1905 and 1911 Castellani of Ceylon described three new microorganisms of the above group: the *Bacterium columbense*, the *Bacillus asiaticus I*, and the *Bacillus asiaticus II*. The last two were isolated from four cases of fever of uncertain origin, in which the possibility of typhoid, paratyphoid, or undulant fever, or of malaria

was excluded. The *Bacillus asiaticus I* was present in two cases of greatly prolonged fever, intermittent and remittent respectively; the *Bacillus asiaticus II* was isolated from two cases which had at first been regarded as instances of protracted typhoid, but in which there was neither enteritis, roseola, nor splenic tumor. The Widal reaction was negative as were likewise the attempts to make a differential diagnosis with reference to typhoid and paratyphoid fevers. The *Bacterium columbense* was isolated from three cases closely resembling typhoid fever (pyrexia falling by lysis, splenic tumor in two cases, and constipation or mild diarrhea) and agglutination tests with the sera from cases of infection with the *Bacillus paratyphosus A* or *B*, the *Micrococcus melitensis*, and the *Bacillus asiaticus I* or *II* were negative.

Cultures of the new microorganisms were sent to the Pathological Laboratory of the Royal Institute in Florence, Italy, and were there studied by G. B. Carlo Fulle, who reports his results in *Lo Sperimentale*, January 20, 1915. He finds that the three bacteria are actually three new and distinct species differing in their morphological and cultural characteristics and in their immunizing reactions from all the other members of the colon-typhoid group. In their cultural features the asiatici approach the typhoid bacillus and somewhat also the paratyphosus B. In the absence of motility they resemble the members of the dysenteric group. The *Bacterium columbense* is a motile organism presenting certain coliform characteristics such as the fermenting of lactose. There is evidence of a slight virulence of the new microorganisms with reference to the rabbit. The reactions of agglutination and of deviation of complement show that the new microorganisms are distinct from one another and from the other members of the typhoid-colon group. There appears to be a community of receptors for the three new bacteria, and a closer affinity between the two asiatici than between either of these and the *Bacterium columbense*.

Statistics of Venereal Infection in the War.

Mobilizations in times of peace are fruitful occasions for the spread of venereal diseases. As for similar experiences in the present war we must be content with individual reports. For example, at the very outset in Strassburg a special hospital with 550 beds for these diseases was provided. From Aug. 1 to Dec. 1, 912 patients were admitted, of which gonorrhea claimed 651, syphilis 188, and chancroid 73. But few cases were of local origin. The work of the troops concerned was mobilization, operation, and occupation, and it was during the occupation of foreign territory that the worst cases were contracted. The measures for checking the perils of occupation are all reducible to keeping the sexes as much apart as possible, and supervising both sexes in regard to health. Wolff read a paper on this subject at a recent meeting of medical men at Strassburg (*Muenchener medizinische Wochenschrift*, February 4), in which he gave the facts above cited. Jaenicke stated that the frequency of venereal diseases in the various armies was as follows, beginning with the greatest offenders: English, Russian, Austrian, French, Prussian, and Bavarian. Jacobi set the greatest value on individual prophylaxis. For prevention of gonorrhea he recommended protargol, of syphilis sublimate ointment. There was considerable difference of opinion at the meeting as to how far cases could be treated at the front. There was general argument, however, that if gonorrhea was treated in special reserve hospitals it might be months before the men could be pronounced cured.

News of the Week.

Report of the Treasurer of the Committee of American Physicians for the Aid of the Belgian Profession for the week ending April 24, 1915:

Dr. George W. Crile, Cleveland, Ohio	$100.00
Salt Lake County Medical Society (third contribution), Salt Lake City, Utah	21.00
Dr. C. P. Thomas, Los Angeles, Cal.	5.00
Portland Medical Club, Portland, Me.	25.00
Dr. C. H. Henninger, Pittsburgh, Pa.	5.00
Dr. J. J. Buchanan, Pittsburgh, Pa.	25.00
Receipts for the week ending April 24th	$181.00
Previously reported receipts	6,324.50
Total receipts	$6,505.50
Disbursements for the week ending April 24th:	
80 Standard boxes of food at $2.30	$184.00
Previously reported disbursements:	
1625 Standard boxes of food at $2.20	$3,575.00
1194 Standard boxes of food at $2.30	2,746.20
Total disbursements	6,505.20
Balance	$0.30

Through an error in the report of April 17th, the contribution of The Bennington County Medical Society, Bennington, Vt., was credited to the Secretary, Dr. Lucretius H. Ross.

For National Quarantine.—A largely attended meeting was held at the Academy of Medicine on April 20 to discuss the advisability of the transfer of the quarantine at this port from State to Federal control. Speeches were made in favor of the transfer by ex-President Taft, Henry James, Jr., and Dr. William C. Woodward, Health Officer of the District of Columbia, and many letters from representative physicians and civic organizations throughout the country were read, all indorsing the efforts of the Academy to effect the transfer. The Academy also adopted resolutions urging the Governor of the State to take immediate steps looking to this end.

The Plague in Turkey.—It is reported that bubonic plague is prevailing to a very alarming extent in Constantinople and elsewhere in Turkey and that it is spreading rapidly. Several cases are reported from Salonica.

Typhus Fever in Serbia.—It is stated that the epidemic of typhus fever shows no sign of abating in Serbia, and an appeal has been made for 1,500,000 suits of underclothing to be used in the fight against the disease. The number of physicians who have died of typhus during the present epidemic is thus far 102. The British Government has sent thirty physicians and the French Government fifty to combat the disease. This is not purely altruistic but is largely a measure of self-protection, as it will be less difficult to strangle the epidemic while it is still confined to Serbia than to conquer it should it reach the armies in Western Europe. Dr. Richard P. Strong, head of the American Commission recently sent to Serbia to study typhus, has arrived at Nish, where he was received by representatives of the Foreign Office and the Ministries of War and Interior and by the president of the Serbian Red Cross Society.

Killed by an Ambulance.—A rapidly moving hospital ambulance struck a stationary automobile one evening last week and threw the latter against

a woman standing on the sidewalk, fracturing her skull and inflicting other probably fatal injuries. The driver of the ambulance was found to have no chauffeur license, although he was in the employ of a large hospital.

Congratulations to Dr. Stephen Smith.—The founder of the American Public Health Association, Dr. Stephen Smith, recently received the following resolutions which were passed at the last meeting of the association, held at Jacksonville, Fla., in December:

Resolved, That the American Public Health Association desires to extend to Dr. Stephen Smith, one of the first organizers of this Association in 1872, its congratulations on his continued enjoyment of health and its joy and pleasure in being able to illustrate the outcome of his efforts and those of his colleagues in the present prosperity of the Association, which has expanded until it represents the public health interests of four countries and of one hundred and twenty-five million people.

Resolved, That the Association wishes Dr. Stephen Smith all of the happiness which the contemplation of a life spent in public service for the amelioration of the sufferings of mankind may bring.

Prof. William T. Sedgwick, Boston, *President.*

Prof. S. M. Gunn, Boston, *Secretary.*

Dr. Harold B. Myers has been appointed professor of materia medica and pharmacology at the University of Oregon, and Dr. Howard D. Harkins professor of biological chemistry at the same institution.

Dr. Samuel T. Darling, formerly chief of laboratory on the Canal Zone, has been sent by the International Health Commission of the Rockefeller Foundation to the Malay States for the purpose of studying tropical anemia and other diseases in the Far East.

Dr. J. George Adami of McGill University has been appointed editor of a medical history of the war and has gone to England to begin his work in the British War Office.

Patronage des Blesses is the name of a society in Paris organized for the purpose of securing aseptic first aid for the wounded and of supplying hospitals at the front with radioscopic apparatus and with thermometers, autoclaves, and other necessary sanitary material. The radiological service was organized by Mme. Pierre Curie. The Museum of French Arts in this city has issued an appeal for subscriptions for the purchase of another automobile circulating laboratory to be presented to the society. Subscriptions may be sent to the treasurer of the museum, Mr. Frank W. Knolhoff, 402 Madison avenue.

Brevium.—It is announced in Boston that Professor Goehring of the Physico-Chemical Institute at Karlsruhe announces that he has discovered a new chemical element, which he calls brevium. It is radioactive and is a disintegration product of uranium.

Salvarsan in England and France.—Owing to the impossibility of getting this drug from Germany the governments of England and France suspended the patent and granted a license to two firms to manufacture the product. In England the drug is now made and sold under the names kharvisan and neokharvisan and in France as arsenobenzol-Billon and novarsenobenzol-Billon. The sale of the drugs is permitted in England on the condition that all samples are submitted to biological tests by an authority approved by the government.

The Death Rate in New York City during the week ending April 17 was unusually high, chiefly owing to the prevalence of influenza. The number of deaths reported during the week was 1,778 as against 1,566 during corresponding week of 1914, the death rate increasing from 14.63 to 15.98 per one thousand of the population. The death rate for the first sixteen weeks of 1915 was 14.66 per one thousand of the population as against a rate of 15.47 during the corresponding period of 1914, a decrease of .81 of a point; the decrease in the death rate for this year up to the last week of March was 1.5 of a point, so that the effect of the increased virulence of influenza during the past three weeks has been to change this decrease in the death rate by almost 50 per cent, from January 1 to date.

A Haul of Alleged Quacks.—Forty-three irregular and advertising practitioners of medicine, some licensed to practice, others not, were rounded up by the police in one afternoon last week and held for examination as law breakers. Many of them were associated with "anatomical museums" or "medical museums" and the latter places were closed by the police as constituting public nuisances.

The American Section of the International Association of Medical Museums held its eighth stated meeting in St. Louis on April 1. Thirty-two papers were presented dealing with Museum Technique, Microscopic Technique, Illustration Medical Teaching, Museum Research, and Special Exhibits. The American Association of Pathologists and Bacteriologists held its meeting in St. Louis at the same time.

The A. Jacobi Division for Children of the German Hospital.—In a notice of the opening of this building last week it was stated that the hospital was planned by Dr. Charles Goodman. We should have said Dr. A. L. Goodman of 136 West 87th street, who is attending physician of the division.

A Medical Assistant for the District Attorney.—Governor Whitman has signed the Mills bill authorizing the District Attorney of New York county to appoint a medical assistant whose duty it shall be to report on all cases of suspicious death or injury coming under the jurisdiction of the District Attorney. Dr. Otto H. Schultze has been appointed.

American Gastro-Enterological Association.—The eighteenth annual meeting of this Association will be held in Osler Hall, Medical and Chirurgical Building, Johns Hopkins University, Baltimore, Md., on May 10, 1915. Physicians are cordially invited to attend. Those desiring further information may apply to the secretary, Dr. Franklin W. White, Boston.

A Meeting Commemorative of the Twentieth Anniversary of the Discovery of the X-Ray will be held at the New York Academy of Medicine, Hosack Hall, on May 5, 1915, under the auspices of the Roentgen Ray Association of Greater New York. The following addresses will be delivered: "The Influence of Roentgen's Discovery on Physical Science," by Prof. Bergen Davis of Columbia University; "Roentgen's Discovery, Its Recent Developments and Future Possibilities," by Wm. D. Coolidge, Ph.D., of Schenectady, N. Y.; "Historical Review of the Development of the *X*-Ray Tube" (illustrated by lantern slides), by H. Clyde Snook, Ph.D., of Philadelphia, Pa.; "The Physical Characteristics of Roentgen Radiation with Reference to the Questions Involved in Treatment," by Prof. J. S. Shearer of Cornell University; "The Influence of Roentgen's Discovery on Medicine," by Ludwig Kast, M.D., of

New York; "The History and Development of the Art of Roentgen Ray Diagnosis," by Percy Brown, M.D., of Boston, Mass. The secretary of the association is Dr. I. S. Hirsch, 96 Park avenue, New York City.

American Association for Promoting Hygiene and Public Baths.—The fourth annual meeting of this association will convene at the New York City Hall, on Tuesday, May 11, at 10 A.M. At the evening session of that date to be held at the New York Academy of Medicine, addresses will be made by his Honor Mayor John Purroy Mitchell, the President of the Association, Dr. Simon Baruch, and others. Physicians are cordially invited to participate in the discussions.

Prize Essay on Social Hygiene.—A prize of $1,000 is offered by the Metropolitan Life Insurance Company to be awarded to the author of the best original pamphlet on social hygiene for adolescents between the ages of twelve and sixteen years. Competition for this prize is open to all. The Metropolitan Life Insurance Company desires to use the winning pamphlet among its industrial policy holders. The Committee of Judges, to be selected by the American Social Hygiene Association, will conduct the competition in accordance with the following conditions: Contest closes July 31, 1915. Manuscripts should not exceed 3500 words and must be in English and must not have been previously published. They must be typewritten on one side only of plain white paper 8″ x 10½″, and must be paragraphed and punctuated for submission as "copy" to printer. More than one manuscript may be submitted by the same author. The winning manuscript, in consideration of the award of $1,000, becomes the property of the donor of the prize, all rights therein being surrendered by the author. The right to purchase any manuscript submitted, at the rate of 5c. a word, is reserved by the Metropolitan Life Insurance Company and by the American Social Hygiene Association. Manuscripts and requests for further information should be addressed to the American Social Hygiene Association, 105 West 40th Street, New York City.

The Late Dr. Peck.—The following resolutions were passed at a recent meeting of the Medical Board of the City Hospital: *Whereas*: It has pleased Almighty God to remove from the sphere of his earthly usefulness our Colleague Edward Sprague Peck, M. D., who for thirty-five years served the City Hospital as Attending and Consulting Ophthalmic Surgeon, and *Whereas*: The Medical Board of the City Hospital desires to express its feeling of personal sorrow and professional loss, therefore be it

Resolved, that in the death of Dr. Edward Sprague Peck the Board has lost an Associate of genial personality, high character, and scientific attainments. *Resolved* that the Board extends to members of his family its sincere sympathy and condolence in this hour of grief and sorrow. *Resolved:* That this preamble and Resolutions be entered in full upon the minutes of this meeting and that copies be sent to the local Medical Journals for publication and to the family of our deceased colleague.

Richard Kalish, M. D., Chairman,
Charles E. Quimby, M. D.,
Daniel S. Dougherty, M. D.,
Committee.

Mr. Bernard Roth, the well known London orthopedic surgeon, died recently at the age of 63 years. He was in active practice for twenty-seven years in both London and Brighton with office hours in London in the forenoon and in Brighton in the afternoon.

Obituary Notes.—Dr. GEORGE WILLIAM MARSHALL of Milford, Del., a graduate of the Jefferson Medical College, Philadelphia, in 1876, a member of the Board of Trustees of Delaware College, ex-State Commissioner of Insurance, and a member of the American Medical Association, and the Delaware State and Sussex County Medical Societies, died at his home on April 18, aged 61 years.

Dr. JOHN ANDREW RANDOLPH of Willow, Cal., a graduate of the Missouri Medical College, St. Louis in 1884, a member of the American Medical Association and the Medical Society of the State of California, and a member and former president of the Glenn County Medical Society, died at his home on April 10, aged 65 years.

Dr. RICHARD POTTS DANIEL of Jacksonville, Fla., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1851, a surgeon in the Confederate Army during the Civil War, and a member of the American Medical Association, the Florida Medical Association, and the Duval County Medical Society, died at his home, after a long illness, on April 10, aged 87 years.

Dr. JEFFERSON D. WRIGHT of Louisville, Ga., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1882, died at his home on April 14, aged 55 years.

Dr. WILLIAM H. CARTER of Altoona, Ia., a graduate of the American Medical College, St. Louis, in 1880, died at his home suddenly on April 11, aged 76 years.

Dr. CHESTER ALFRED MAYER of Louisville, Ky., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1881, and for many years a member of the Kentucky State Board of Health and of the Faculty of the Southwestern Homeopathic Medical College, died on April 10, aged 58 years.

Dr. JOHN L. BROWN of Mt. Sterling, Ky., a graduate of the University of Louisville, Medical Department, in 1865, died at his home, from paralysis, on April 13, aged 52 years.

Dr. CHARLES L. EDWARDS of Sebree, Ky., a graduate of the Missouri Medical College, St. Louis, in 1866, and a member of the Kentucky State Medical Association and the Webster County Medical Society, died suddenly, while attending a patient, on April 12, aged 52 years.

Dr. CHARLES W. RAY of Springvale, Me., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1881, and a member of the Maine Medical Association and the Piscataquis County Medical Society, died at his home, from pneumonia, after a short illness, on April 10, aged 55 years.

Dr. JOHN JOSEPH HECTOR MCALLISTER of New Bedford, Me., a graduate of the Harvard University Medical School, Boston, in 1903, and a member of the Massachusetts Medical Society and the Bristol South District Medical Society, died at his home, after a short illness, on April 16, aged 39 years.

Dr. DANIEL FRANCIS LEE of Omaha, Neb., a graduate of the University of Nebraska, College of Medicine, Omaha, in 1902, former county physician and city physician of Omaha, and a member of the Nebraska State Medical Association and the Omaha-Douglas County Medical Society, died at his home, after a brief illness, on April 13, aged 37 years.

Dr. CHARLES C. KNIGHT of Peekskill, N. Y., a

graduate of the New York University Medical College, New York, in 1855, consulting physician to the Peekskill Hospital, and a member of the American Medical Association and the New York State and Westchester County Medical Societies, died at his home on April 21, aged 82 years.

Dr. JOHN MILLER FAISON of Faison, N. C., a graduate of the University of Virginia, Department of Medicine, Charlottesville, in 1884, a member of the Medical Society of the State of North Carolina and the Duplin County Medical Society, and a former president of the latter, died at his home, suddenly, on April 21.

Dr. GEORGE COLEMAN ABELL of Texarkana, Tex., a graduate of the Hospital College of Medicine, Louisville, Ky., in 1890, and a member of the American Medical Association and the Arkansas Medical Society, died at his home, from meningitis, on April 10, aged 54 years.

Dr. DAVID STUART died at New Castle, Del., on April 9, at the age of 70 years. He was graduated from the medical department of the University of Pennsylvania, in the class of 1872.

Dr. EUGENE T. OLIPHANT of Bridgeport, N. J., died at Cooper Hospital, Camden, on April 11, at the age of 66 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1875.

Dr. MAX JOHANNES WALTER died at Philadelphia in an attack of apoplexy on March 17 at the age of 41 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1912. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. SAMUEL S. O. WARREN of Roy, Wash., died at his home on April 10, after a short illness, aged 76 years.

Dr. JAMES S. IRVIN of Danville, Va., a graduate of the University of Virginia, Department of Medicine, Charlottesville, in 1893, and a member of the American Medical Association, the Medical Society of Virginia, the Danville Academy of Medicine, the Southern Surgical and Gynecological Association, and the American College of Surgeons, died suddenly at the General Hospital, Danville, shortly after having completed an operation, on April 10, aged 45 years.

Dr. LORENZO W. PHINNEY of Wappinger's Falls, N. Y., a graduate of the Geneva Medical College, Geneva, N. Y., in 1866, a member of the American Medical Association and the New York State and Dutchess County Medical Societies, and physician to the Gallandet Home for Deaf Mutes, died at his home on April 20, aged 74 years.

Dr. AMOS PATTERSON WEBBER of New Bedford, Mass., a graduate of the Bellevue Hospital Medical College, New York, in 1883, a member of the American Medical Association, and the Massachusetts and Bristol Districts Medical Societies, and attending physician to St. Luke's Hospital, New Bedford, died at his home, after a long illness, on March 20, aged 55 years.

Dr. GEORGE DICKINSON THAYER of Northampton, Mass., a graduate of the New York University Medical College, in 1881, city physician of Northampton for nine years, and county physician for thirty-two years, one of the staff of the Dickinson Hospital, and a member of the Massachusetts and Hampshire District Medical Society, died suddenly at his home on March 15, aged 57 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

REPORT OF PARLIAMENTARY COMMITTEE ON PATENT MEDICINES—CEREBROSPINAL FEVER—ARCHITECTS' INSTITUTE ON NEW BUILDINGS OF KING'S COLLEGE HOSPITAL—OBITUARY.

LONDON, April 9, 1915.

THE report of the Select Committee on Proprietary Medicines, though mentioned from time to time, seems scarcely to have received adequate notice, for it is very full and deserves careful consideration. To set a committee to inquire into the sale of patent and proprietary medicines, preparations, appliances and advertisements relating thereto, was no light task, but to that was also added the state of the law on the matter, and whether any amendments were necessary or desirable, and if so, what? The committee set to work with commendable energy and organized their proceedings. They have held thirty-three public sittings, and examined forty-two witnesses, to whom they put 14,000 questions. These are summarized in the report which, with other matter, extends to twenty-eight pages, many of which are occupied with the recommendations. The leading one of these is that the administration of the law governing the advertisement and sale of all secret and proprietary medicines and appliances be co-ordinated and combined under the authority of one Department of State. This would be undertaken most naturally by a Ministry of Health, but hitherto we have not set up such an authority. The report, however, takes it for granted that such a department will be created, and goes on to advise that in the meantime the work be committed to the Local Government Board. Another recommendation which causes perturbation among those concerned is that there shall be kept at the department a register of manufacturers, proprietors and importers of patent, secret and proprietary remedies, and every such person must apply for a certificate of registration, to obtain which an exact, complete statement of the ingredients and their proportions in every such article must be made, other than wine and the alcoholic strength of medicated wines. Further the therapeutic claims made or to be made must be fully stated, and a specimen of every appliance for the cure of ailments other than recognized surgical appliances must be furnished to the department or Ministry of Health. But this information as to the real nature of secret remedies will not be disclosed except under special circumstances, but will be controlled by analyses of government chemists. A court is to be constituted to permit or prohibit, in the public interest or in support of the law, all such secret or proprietary articles, to every one of which will be assigned a special number, which must be printed on every bottle or package. Inspectors will be placed at the disposal of the department or ministry to examine advertisements and observe the sale and other points connected with the articles. There are some other recommendations, but these are enough to make one wonder that a committee should officially propose them, and to heave a sigh on asking oneself if any or how many one may hope to see adopted in this generation.

Cerebrospinal meningitis, which is becoming more commonly called cerebrospinal fever, is not exactly a rare disease in this country, and though we have from time to time slight epidemics they are neither

so severe nor so extensive as are reported to us from your side. The danger of spreading is, however, so distinct as to call for decisive measures directed against the extension. Some cases for the last month or more have been reported from different localities, and the Public Health Committee of the Local Government Board have issued a revised memorandum of that formerly circulated as to the measures recommended by their medical officer to prevent the spread of the disease. As it chiefly occurs in small and distinct outbreaks, there are many medical men who have not met with it in practice, or not for several years, so that there is some danger of the early cases not being properly diagnosed. To promote early recognition the County Council are prepared, on the request of the Medical Health Officer of the locality, to send a medical officer to collect material from the throats of contacts for bacteriological examination in their own laboratory, and also samples of cerebrospinal fluid from suspects. Obviously, this is the most reliable means of determining the diagnosis, and when there is meningitis the attendant may well be glad to avail himself of such assistance. A number of other important statements make this official memorandum valuable.

Mr. W. A. Pite read a paper at last week's meeting of the Royal Institute of British Architects on the new King's College Hospital. He pointed out that though the grand pile of Thomas Bellamy was no more, its fine traditions, associated with the names of Lister, Todd, Fergusson, Priestley and many others, had transferred themselves to the new buildings. I may compliment him as their architect. It is the first example in this century of the removal of one of the large general hospitals from a crowded central district of London to one of its suburbs, where such an institution was needed, and where, with our modern methods of transit, it can easily be reached.

Surgeon-Colonel C. P. Costello died on the 1st inst., in his 80th year. He had seen much active service in India. He was at the forcing of the Umballa Pass in 1864, and took part in the Jawak Expedition, 1877-78; went through the Afghan war, 1878-80, and was mentioned in dispatches for his work eleven years later in the Manipur Expedition. His son, Major E. W. Costello, also of the Indian Army, received the V. C. for his work in the defence of Malakand.

Sir John Lentaigne, a past president of the Royal College of Surgeons in Ireland, died suddenly on the 30th ult., aged 59. He was for many years surgeon to the Mater Misericordiæ Hospital, and held other important posts, among them consulting surgeon to the Royal Hospital for Incurables.

Several other deaths of well-known members of the profession have lately occurred. Among them Sir George Turner, well known for his great services in South Africa, during his work in connection with leprosy; Dr. W. Murray Dobie of Chester, on the 12th inst., aged 86. In the epidemic of cholera at Chester in 1867 his work was greatly appreciated. Later he was made a freeman of the city and his portrait presented to him. He had long been a J. P., and was greatly esteemed by the citizens throughout a long retirement from work. Dr. Lewis Jones, on Easter Sunday, aged 58. He was consultant of the electrical department at St. Bartholomew's Hospital, past president of the Electro-Therapeutical Society and delegate of the British Government to the Congress at Liege, 1905, and of Paris, 1910.

1. A New Preparation for Pyelography. — E. L. Young, Jr., believes that collargal and other soluble silver salts are absorbable poisons when injected into the renal pelvis. About one and a half years ago Kelly and Lewis reported the use of a 5 per cent. emulsion of silver iodide for pyelography. They claimed that it was non-irritating and gave a good shadow. Others who tried it found it impossible to use satisfactorily, for when the mucilage was stiff enough to hold the iodide in suspension, it was too stiff to use, and when thin enough to inject, it was worthless as a suspension and, moreover, had the danger of leaving behind in the pelvis a foreign substance. The necessary requisites are: a substance in itself nonirritating and sterile, sufficiently fluid to flow easily through a ureter catheter, and easily and quickly soluble and diffusible in water in order to fill evenly a kidney pelvis, not form any coagulum, and to leave the kidney pelvis as readily. Mucilage of quince seed was selected as offering the greatest possibilities. This was the vehicle used by Siter in 1905 when he used silver iodide in urethritis. The author, in collaboration with Godsoe, found, however, that any mucilage they made always became contaminated with a fungus in a short time. Moreover, dilution with water to make thin enough to use resulted in a poor suspension. The following is the method used by Godsoe: Quince seed, 100 grains, water 8 oz. Macerate for 24 hours with frequent agitation. Do not crush the seed. Strain through cloth. Add 2 per cent. boric acid up to 20 ounces. It is important to extract with water and not with the boric acid solution, as boric acid solution does not make a good mucilage. Enough of this mucilage is added to 12½ c.c. of argentide to make 50 c.c., and vigorously shaken for two minutes. Again, the shaking is an essential part of the process. The resulting emulsion lasts several weeks, and is a thin, clear fluid flowing readily through a ureter catheter. It is on the method of preparation and the character of the resulting emulsion that the value of this substance depends.

3. Misapplied Bone Surgery.—H. Augustus Wilson concluded that in order to lessen or prevent misapplied operative orthopedic surgery, the following facts should

be remembered: Operations are rarely necessary in cases of fractures that have been treated on scientific principles from the onset. Before operating for non-union, definite radiographic information should be obtained concerning the presence of callus, as well as that of bone atrophy involving the fractured bone or neighboring bones. Bone transplants, or other operations for securing ankylosis, are not applicable to the early stages of bone tuberculosis, when functional recovery may be obtained with the control of the pathological process. When it becomes apparent that the pathological process has proceeded to an extent beyond the possibility of functional restoration, ankylosis may be secured by either the brilliantly conceived Hibbs operation or that of Albee of broader application. Ankylosing methods do not cure the bone tuberculosis, and therefore they must not be relied upon solely, but must be associated with prolonged fixation and other accepted methods of treatment. Before resorting to any operation, except in an emergency, a consultation should be held, preferably with the attending internist. When operative procedures are finally determined upon, the patient should be told the truth concerning his operation. If this information were reduced to writing and duly signed by those participating in the consultation, the total number of operations might be reduced, but the impressions that patients often appear to entertain in regard to the functional results obtainable would be removed.

1. Chemotherapy of Tumors.—R. Weil reviews the history of the treatment of tumors by chemical preparations, which treatment has recently been investigated by Wassermann and his followers. An accidental observation led Wassermann to believe that selenium possesses a high degree of affinity for tumor cells, and he devised a method for carrying it into the blood by the use of an eosin combination. Wassermann has not followed up his work with a scientific report, and it has been extensively criticized by Keysser and others. A number of observers, however, following Wassermann's suggestion, have reported striking therapeutic effects from various chemical substances. Keysser's criticisms have been reviewed by Weil, who says that all of the facts taken together constitute a very remarkable and convincing piece of scientific investigation, permitting of but one conclusion, and that is that none of the preparations which claim to be therapeutically effective, exercises any direct influence on the life or development of the tumor. Under certain definite and restricted conditions, however, they do seem to produce certain changes in the tumor, and even cures in a small proportion. In subcutaneous tumors, not smaller than a cherry pit in size, Keysser thinks that this is due to the constant palpation and examination of the growths, causing circulatory changes leading the injected substances to lodge in the tumors, and therefore causing or helping autolysis. The author does not consider this explanation final. He has found that some other substances seem to gather in the necrotic parts of the growths, which might well undergo liquefaction under their influence, without having any direct effect on the vitality of the living part. The small percentage of cures reported is explained by the emphasis on the fact that 95 per cent. of the experimental animals die under the treatment, and the necrotic areas and those with such a tendency, like foreign growths in general, would be especially liable to be affected. It has been largely assumed that metals take a colloidal state in the tumors, and in this form have a peculiar characteristic influence in their destruction, which theory he rejects. Clinicians have followed up the experimental attempts, working with selenium in the colloidal form. These preparations seem to produce but slight disturbance as a rule, and their effects have been reported as encouraging. It has of course been impossible to duplicate the large doses used in animals, and the author suggests as an explanation that the mental effect is largely responsible. He believes that the demonstrable reduction in size of a tumor, of a kind not to be attributed to the natural processes of evolution of that tumor or of its associated lesions, is the one essential feature of effective therapeutic intervention. Using this standard, it is apparent that none of the methods above discussed can lay claim to therapeutic effectiveness. The modifications attributed to them occur spontaneously in a large proportion of cases as a result of a natural evolution of the disease process, and this is a fact which cannot be too strongly emphasized, and is likely to be overlooked by optimistic physicians in a hopeless disease like cancer.

2. Bacillus Coli in Pasteurized Milk.—L. P. Shippen finds that, as observed by De Graef and De Jong, certain strains of *B. coli* are not killed by a temperature exceeding that commonly used in pasteurization. The thermal death point of this and similar organisms is not a constant quantity but varies for different strains of the same bacterium. In the case of *B. coli communior* this variation was found to be as great as thirteen degrees. The presence of *B. coli* in pasteurized milk cannot be taken as an index of its improper pasteurization or subsequent contamination.

3. The Small Heart in Tuberculosis.—F. M. Pattenger advances the hypothesis that the small heart in tuberculosis is the result of compensatory circulatory changes, believing that the correctness of this explanation is supported by the fact that the small heart is also found in enteroptotic persons. The action of the inspiratory enlargement of the thorax increases the negative pressure in the thoracic cavity and dilates the large veins and heart chambers. The interference with respiration in pulmonary disease and of the contraction of the diaphragm by enteroptosis causes an interference with the suction action of the intrathoracic vessels, and a smaller amount of blood is delivered to the heart. That the heart is an organ which adapts itself to various circumstances is undoubtedly true, and the organ undergoes a compensatory contraction under the above conditions. The small heart is a result and not a cause of tuberculous infection.

4. Acute Osteomyelitis.—J. P. Warbasse, in discuss-

ing this disease, emphasizes the following facts: The diagnosis is easy, the treatment simple, and the cure effective. Two symptoms are sufficient for its recognition: pain of rapid onset, usually in the end of a long bone; and fever, often high, are characteristic. The blood picture and prostration of serious infection are present, and local tenderness follows the pain. Redness and swelling appear only after the moment advantageous for treatment is long past. Any marrow bone may be affected, and the *x*-rays are not necessary or of special value for early diagnosis. It is a common disease, especially afflicting the poorly nourished. Many surgical diseases recover without surgery. Some are made worse by surgery. But acute osteomyelitis is most easy of diagnosis from the very beginning. It invariably does badly unless treated surgically. Its treatment is so simple that surgery at its worst cannot do as much harm as the disease. In most surgical procedures skill is the important factor, but in acute osteomyelitis, expedition is the one prerequisite for success.

5. **Leucocytosis in Abdominal Hemorrhages.**—L. A. Levison concludes that a leucocytosis should not be relied on as a differential point when the clinical signs demand the differentiation of appendicitis or other inflammatory trouble in the abdomen from an intra-abdominal hemorrhage. Leucocytosis due to intra-abdominal hemorrhage is to be distinguished from the posthemorrhagic leucocytosis which follows any severe bleeding. Leucocytosis from intraabdominal hemorrhage comes on within twenty-four hours and lasts until the second day. It is ascribed to an irritation of the blood-forming organs by the absorbed constituents of the blood. The peritoneum may be a factor in the formation of white cells. The morphological blood picture is not changed.

12. **Subdiaphragmatic Inflammation without Suppuration.**—R. I. Lee has had the opportunity of observing four cases which all gave a similar syndrome of physical signs and a similar roentgenogram. All four were considered at first to be suppurative processes. All, however, recovered spontaneously. These cases indicate that there are inflammatory processes of infectious origin situated below the diaphragm which do not necessarily go on to suppuration. At any rate they recover spontaneously. The signs might well be interpreted as having their origin above the diaphragm, and it is to the *x*-rays that one owes the ability definitely to decide that the process is below the diaphragm. While the statement of Picqué that subdiaphragmatic inflammation is a direct indication for surgical procedure holds true in a large proportion of cases, yet apparently there is a group of cases of subdiaphragmatic inflammation not hitherto recognized that recover spontaneously. This group of cases seems to form a clinical entity. The last two cases of the author's series were recognized clinically. The diagnosis was made by the clinical signs. It is probable that on account of the difficulty of differentiating processes above the diaphragm from those below the diaphragm without the use of the *x*-rays, this group is larger than at first appears. The roentgenogram is that of subdiaphragmatic abscess. The differentiation of this particular group of cases from the usual type of subdiaphragmatic abscess must be made on clinical evidence.

1. **Wound Infections.**—Sir A. E. Wright states that in the present war practically every wound is heavily infected. A special outstanding feature is a mixed infection of streptococci with fecal organisms, chiefly the gas-phlegm bacillus and the tetanus bacillus. The presence of these microbes makes the first period of the wound infection—the period of imprisoned discharges—a specially critical time for the patient. As soon as a free outlet has been provided and aerobic conditions have become established in the wound its bacterial flora changes. The ordinary pyogenic infection gains the upper hand, and instead of an infection of the imprisoned discharges one now has an infection of the granulating wound surfaces and of the flowing discharges. The chief bacterial agents here at work are the streptococcus and staphylococcus and *Bacillus proteus*. In the treatment of these wound infections there are three different therapeutic measures: treatment by antiseptics; treatment by physiological methods, such as opening up and draining of the wound, which bring the antibacterial powers of the blood to bear on the infecting microbes; and lastly, treatment by vaccine therapy and similar methods. The second method is the most important. By means of a special technique, which consists essentially of a method of making anaerobic cultures in capillary tubes, the author sought to answer the question, Can the microbes which are found in wound infections live and multiply in the unaltered blood fluid? Serum cultures made by this method furnish a very striking and uniform result. One obtains in the cultures implanted with the higher dilutions of the pus a pure culture of the streptococcus, and in the cultures more heavily implanted with the pus the streptococcus mixed with a certain number of other microbes; in particular, a few staphylococci and an anaerobic wisp-like diphtheroid bacillus, which often is abundant in pus, being found both intracellularly and extracellularly. All the other pyogenic microbes appear to be inhibited in undiluted normal serum, and when they put in an appearance it is only after fairly heavy sowings with pus, and comparatively late. Out of these facts comes a practically important classification of pyogenic microbes—a classification into, on the one hand, *serophytes*, and, on the other, *serosaprophytes*. The serophytes would be those which, presumably because they find their foodstuffs ready made in the blood fluids, are at home there, and can in the absence of phagocytes grow and multiply there without restraint, or practically with restraint. The serosaprophytes would be those which cannot grow and multiply in the blood fluids until a change which one may, pending nearer investigation, call simply a degenerative change, has passed over those fluids. The next question that presented itself to the author was: Does the lymph which pours into the wound provide a favorable nutrient medium for the microbes which have been growing in that wound? Experiment provides an affirmative answer. The next problem to be determined is the cause of that "corruption of the lymph" which converts it into a favorable nutrient medium for serosaprophytic microbes. This cause the author believes to reside in the reduction in the antitryptic power of the lymph. The antitryptic power of the blood would appear to be increased in every case of severe wound infection. This is perhaps a defensive reaction of the organism directed against a possible invasion of the blood by serosaprophytes.

2. **War and Cholera.**—W. J. R. Simpson believes that the remarkable absence of scurvy, dysenteries, and epidemic diseases that has so far characterized the European war gives no assurance that the condition of affairs will continue in the coming summer and autumn, or in the succeeding year. A combination of war, flood, and earthquake, ending in famine in some localities, and in scarcity of food in others, is calculated to be a powerful force favoring in due season the manifestation and spread of epidemic diseases. Cholera is not an endemic disease in Europe, but it has visited that continent in nine separate invasions in a little over ninety years. There have been only three wars in Europe coincident with its presence in the area of hostilities: the Russo-Polish War in 1831, the Crimean War, and the Balkan War. The danger of cholera prevailing in the zones of hostilities next August is not a remote one. Measures should at once be taken to prepare to combat this diesase. Preventive inoculations with Haffkine's prophylactic give a very high protection against cholera attacks for at least one year. During the military operations of the Greeks in Macedonia in 1913, a general vaccination of the army and civil population was carried out. Approximately half a million persons were inoculated. Ninety-nine per cent. of the persons inoculated twice remained refractory to the epidemic; and in this way Greece was saved from a serious visitation of cholera.

6. **Meningococci in Peripheral Blood.**—A. C. Coles reports the case of a male, aged 33 years, who died fifty hours after the onset of the first symptoms of a profound septicemia. This was characterized by the chills, vomiting, bodily pains, rise of temperature, and profuse purpuric rash. Meningitis was suspected mainly by the process of exclusion, and also because the disease was epidemic at the time. No mennyococci were found in the cerebrospinal fluid, but antimeningitis serum was injected into the subarachnoid space. The patient became comatose and died. The point of interest in this case is the fact that blood films obtained shortly before death showed typical meningococci.

5. Some Notes on the Treatment of Bites by Venomous Snakes. J. Crofton Fox.

3. **Prophylactic Inoculation against Tuberculosis.**—W. M. Croftan states that it has been his practice for the past eight years to urge the members of families whose parents were tuberculous, or in which cases of tuberculosis had occurred, to undergo a short course of tuberculin. The tuberculin he has used until lately has been Koch's T. R., and the doses he has used for adults have been, as a rule, 0.001 c.mm., 0.005 c.mm., and 0.01 c.mm.; for infants 3 months old 0.0001 c.mm., 0.0005 c.mm., 0.001 c.mm. Sometimes further doses are given. There is sometimes a slight rise of temperature in the evening if the injection has been given in the morning, but otherwise no serious disability. The usual interval is seven days. The improvement in health in many of the members of tuberculous families thus treated has been most satisfactory, and so far no case has occurred among those who have been inoculated, but the numbers are far too small to have any value. T. R., however, is not a very good antigen, nor are any of the ordinary tuberculins on the market. Some years ago the author discovered that tubercle bacilli would dissolve in benzoyl chloride, and that this solution produced very marked focal and general reactions in tuberculous patients. When using it for therapeutic purposes, the initial dose had to be very small—0.0000001 mg. in lung cases, and 0.000001 mg. in extrapulmonary cases. The highest dose that had to be attained was 0.01 mg. The clinical results have been so satisfactory that the author now uses no other for therapeutic purposes. The doses are increased as follows: 0.0000002, 0.0000004, 0.0000006, 0.0000008, 0.000001, and so on. The dilutions are made in liquid paraffin, containing 2 per cent. benzoyl chloride, and the author generally adds 0.032 gram iodoform dissolved in ether, so as to combine immuno- and chemotherapy. For prophylactic purposes the initial doses may be larger and the rises more rapid.

5. **Treatment of Snake Bites.**—J. C. Fox injects a full dose of cocaine hydrochloride at the site of the puncture caused by the fangs of the snake, followed later on by appropriate treatment of symptoms as they arise. J. D. Aitken of South Nigeria has shown the efficacy of cocaine in the treatment of scorpion stings. It not only relieves the very severe pain, but also, if the treatment be immediate or not long delayed, causes a complete absence of the swelling that is usually so rapid and characteristic. Cases which the author has treated with cocaine combined with potassium permanganate include those bitten by *Echis carinatus*, *Naia nigricollis*, and *Bitis arietans*. Cases treated primarily with cocaine alone consist only of those bitten by *Echis carinatus*. At first the author used to incise punctures deeply, and rub into incisions potassium permanganate, and then inject hypodermically a solution of cocaine hydrochloride proximally. In cases of *E. carinatus* venom there was uncontrollable hemorrhage from the incision starting on the second or third day. The incision and the potassium permanganate were omitted in the next case, but there was still troublesome oozing hemorrhage from all mucous surfaces, which reduced the patient to a dangerous state of anemia. For this there were given large doses of a solution of gelatine by the mouth.

Berliner klinische Wochenschrift.

March 8, 1915.

Clinical Observations on Tetanus at the Front.—Goldscheider states that tetanus in animals is at first localized at the point of (experimental) inoculation and this behavior is not uncommon in mankind. Bilbroth knew of tetanus limited to one hand. In amputation cases the disease may begin with twitchings in the stump. There is no doubt that observations like these and the teachings based thereon have been largely ignored or overlooked. The author has never failed to observe the behavior of the muscle groups nearest the wound. Local tetanic phenomena are least likely to occur on the trunk and head. The group of symptoms comprises muscular twitchings, muscular rigidity and increased reflex excitability. Sometimes this picture occurs isolated, sometimes associated with the later developments. The chewing muscles often exhibit this isolated local phase before actual trismus develops, but this is readily confused with everyday sensations. When trismus has actually developed, the injured limb may be found in the stage of local tetanus. In about half of the cases, the increase in induced reflex excitability is marked in the affected limb. This involves the skin, bone and tendon reflexes. Parallel with this is the irritability toward sounds, touch, concussion.

The author devotes a large part of his space to the behavior of the patient toward a great number of reflex phenomena, which he regards as of extreme significance and which deserve monographic consideration. Trismus is not a very trustworthy guide for prognosis in certain cases, although it forms the basis of a good general law. It has been known to fail outright, to constitute the sole symptom, to cease spontaneously before death, etc. There is a trunk type and an extremity type of tetanus in which the muscles of one locality are involved to a much greater degree than those of the other. In both types trismus occurs. The extremity type in reality refers to the lower extremities in the majority of cases, although an arm type also exists. Rose's head tetanus is of course well known. Nevertheless the various local forms are as a rule without type as a study of individual cases shows. Generalized tetanus often occurs and trismus remains the most constant of all symptoms. The site of the wound tends to complicate the extremity types: for example a subject has the lower extremity type with local tetanus in the wounded arm.

The Psyche of the Wounded.—Münzer states that in almost every wounded soldier the psychic condition "goes back" to a greater or less extent. The man feels helpless and abandoned. He wishes himself at the dressing station. His comrades fight onward while he, with the other helpless, is left behind. He must often wait for hours for a stretcher because the crews can do little in the day time in the hail of bullets. He bleeds and thirsts. Minutes pass like hours. At last darkness arrives and he is borne to the dressing station. Even once there he must wait long for a surgeon. The psyche sooner or later passes into a state of apathy, and he is as indifferent to his surroundings as he was acutely influenced by the psychic trauma caused by his sufferings. The slightly wounded soon regain their psychic equilibrium. If the injury is severe enough the subject is of course collapsed from the first. In the ordinarily severely injured the shock of operation is added to the traumatic shock, but the psyche does not participate further. When all shock wears off, which should happen within 24 hours, the psyche is again active and two kinds of behavior are noted. In the first the subjects are quiet, patient, resigned. They crack jokes and are deeply grateful for any little attention. These men are the real heroes of war. The other kind of man shows more or less traumatic neurasthenia. He is irritable, excitable, content with nothing. They wish to go home, complain bitterly when their wounds are dressed. Nevertheless these men are not to be treated as normal subjects. They are ill in mind, very largely as the result of their hardships in the trenches. They may have gone into battle in a famished state as must often happen. In a word they were "all in" before the battle and the wound. The condition of the psyche after the shock is eminently natural to the average man under the circumstances. It is a fact that a larger proportion of wounded officers exhibit this behavior than of wounded troops. The former have a finer, more sensitive organization, and the change of life from peace to war is more of a hardship to them.

Berliner klinische Wochenschrift.

March 15, 1915.

War and Traumatic Neuroses.—Oppenheim gives the status of this subject in civil practice. Then came the war. Did its traumatic neuroses bear out the teachings of civil practice? At first it seemed so. The psychic traumas of war seemed to affect the predisposed. But presently it began to be noted that these neuroses attacked many who were of sound stock. The insults of the battle are mechanical, psychical, or mixed. A detonation, for example, affects the auditory nerve by concussion, and also shocks the psyche by the fright engendered. Aside from the frequent absence of predisposition there is a sufficiently close conformity between the traumatic neuroses of peace and war. We do not often see pure types of neuroses. Neurasthenia stands as a rule in the foreground, with its headache, vertigo, insomnia, irritability, sensitiveness to sounds, general weakness and exhaustibility, tremor, vasomotor symptoms, etc. Objectively the symptoms most prominent are increase in the tendon reflexes, and fibrillary twitchings which may go so far as myokymia. Hysteria is manifested in aphonia, mutism, abasia, hemoanesthesia, paresis of extremities. But in some phenomena of psychogenic origin we miss the hysterical character and stigmata. Neurasthenia and hysteria are associated in the majority of cases of traumatic neuroses, in war as in peace. Tics, muscle spasms, and various tremors are common, and may be regarded as in part hysterical, but the author finds that suggestion has little power over them. The motor irritant phenomenon known as spastic neurosis, and which may be manifested as a tonic spasm of the muscles of a limb (giving rise to spastic palsy) is not hysterical, perhaps not even psychogenic in its expression, although probably due originally to psychic trauma. Sudden paralyses in the nonhysterical are common, and the soldier is unable to declare just when the accident occurred. Hence Oppenheim terms it akinesia amestica. Of course, there is nothing to prevent the occurrence of this accident in an hysterical person and the type may be more severe in such. In the nonhysterical cases of spastic neurosis, akinesia amnestica, and reflex paralysis even a long course of systematic treatment sometimes proves to be without effect.

Magnesium Sulphate in Tetanus.—Meltzer, who introduced the use of this remedy for tetanus discusses very fully some of the more advanced aspects of the subject, such as the combination of intramuscular injections with mild ether narcosis. He believes firmly that which some authors profess to deny, that tetanus itself is nearly always the direct cause of death—in other words, death is the result of the convulsions which cause fearful sufferings, prevent nourishment, and wear out the circulation and respiration.

Clinical Observations on Tetanus at the Front.—Goldscheider continues his article, covering the subjects of prognosis and treatment. Concerning the latter he discusses a special group of 23 cases. Of this number 2 were brought in moribund, 2 died of sepsis, 1 died from the severity of the injury, while 8 died of tetanus *per se*. Ten patients recovered. Good care he regards as principally responsible for this showing. Narcotics are of use because they render the nerve cells less susceptible to the action of the tetanus virus. Death is then less likely to occur from the indirect causes of convulsions (suffocation, cerebral hemorrhage, exhaustion). His main narcotic is chloral, always given by enema, lest if taken *per os* it cause suffocatory paroxysms. The author thinks delayed serum injections may be beneficial. He has seen no benefit from magnesium.

Muenchener medizinische Wochenschrift.

March 9, 1915.

Experiences of a German Physician Captured by the French.—Finckh fell into the hands of the French on September 11 along with his staff and dressing pavilion. A French captain who spoke some German told

him it would not be safe to return him to his command at the time, although this could have been done *via* Switzerland. The captain placed a corporal's guard in charge of the dressing station, and the corporal saw that Finckh and his staff were well fed and housed. The corporal, however, could not resist the temptation of buckling on a revolver, flask, etc., belonging to the German staff, and parading up and down before his guard. The German wounded of the dressing station lay in a barn near at hand, and the French soldiers looked on in wonderment but without any expression of resentment. They even shared with them bread and wine. Soon some French surgeons and clergymen arrived on the scene. Upon the author's request dressings were supplied in great quantities, along with camphor, caffeine, and morphine. The French continued to bring in new German wounded, and reported that many still lay on the battlefield who had not eaten nor received medical attention for 4 or 5 days. An officer then took Finckh in his auto to the place and the unfortunates received food and medical attention until the French sanitary corps could come up and take charge. The wounded in the barn fared similarly in the latter respect after an interval of several days. The author was transported with the wounded prisoners and was *en route* three days and two nights. At stops crowds showed curiosity but no further emotions. However, they were relieved of their overcoats, in return for feeding them lavishly. A French surgeon at one station volunteered to take off some of the severely wounded; the others also received fresh dressings. The only insults received in transit were from a few French women. Arrived at the terminus, the author was placed among the German officer prisoners. A great hospital, a ramshackle old structure improvised for the purpose, had to be shored up before receiving the added load of prisoners. Here the author saw his wounded interned. Everything was forlorn and furnishings and conveniences were all wanting. Broken wine bottles served for urinals, old shoes for bedpans. These were emptied into a vat, and the latter was evacuated the next day. The food contained at times maggots and small beetles. Naturally all these deficiencies were remedied, although very slowly. During the author's 8 weeks' sojourn he was constantly striving to improve these conditons. The French surgeons were most willing but powerless. The usual diseases were present, and of the 400 wounded 7 per cent. died; 20 or 2 per cent. developed tetanus and only 3 recovered, one of whom died later of typhoid. The author was treated with the greatest courtesy by his medical colleagues. The latter regard a German military surgeon as a man to be honored and respected. He was allowed his freedom and the privilege of wearing civilian clothing but found no time to leave the hospital. For his work as surgeon, in sparing the French chief much of the labor of treating the German wounded, he received the salary of a French aide-major. Even after having a prospect of returning to Germany, he stayed voluntarily for several weeks to look after his charges. When he was enabled to return his French colleagues accompanied him to the train.

A Simple Prophylaxis Against Lousiness.—Eysell recalls the old observation that workers in sulphur mines escape malaria. It is now easy to see that mosquitoes could not exist in the presence of sulphur vapor which contains more or less hydrogen sulphide. The author now proceeded to dust precipitated sulphur over all body linen and underwear. Garments were reversed and the sulphur brushed in with special reference to seams, etc. As thus applied the sulphur is presumably inert, but when the garments are worn the perspiration activates the sulphur. The latter is also efficacious against bedbugs, fleas, stinging diptera and other vermin.

March 18, 1915.

Subdiaphragmatic Heart Massage. — Weitz states that Lane introduced this resource into medicine in 1902. Cackovic then took up the subject and was able to secure reanimation in nearly one-half of a considerable material. The method is indicated after failure of the usual methods of resuscitation, as tongue traction, artificial respiration, and precardial heart massage. It must be begun before the fateful ten minutes. The chief indication is in syncope following chloroform narcosis. The intervention is of a considerable severity, and therefore dangerous. The author tested it in a case of white narcosis syncope. The patient was a man aged 30, of an old family. He had been wounded by a bullet which had shattered the right tibia. General condition normal. It became necessary to open an abscess at the inner malleolus, and chloroform was the anesthetic. Everything went ahead smoothly. Another abscess formed near by, and some signs of infection came in evidence. This time the chloroform suddenly set up collapse symptoms. Heart and respiration came to a standstill. Tongue traction and Sylvester's method of artificial respiration, and precardial massage were practiced, the palm being struck rhythmically on the precordium, but no improvement could be seen. The epigastrium was then quickly disinfected with iodine, and median laparotomy was performed, the right hand was introduced beneath the flaccid diaphragm, grasping the apex of the heart, while the left hand continued to practice precardial massage by a sort of bimanual manoeuvre. After three minutes there was a general response in the heart action and respiration. Saline infusion and camphor injections were begun as adjuvants. As the circulation was aroused the wound, hitherto bloodless, began to bleed. The patient was kept alive for thirty hours, and whether death was cardiac or respiratory cannot readily be pronounced. The sensorium never became clear. An autopsy, which was refused, might have cleared up the confusion.

Gas Phlegmon of the Pia Mater.—Korbsch describes the following case: On January 1, 1915, a 20-year-old infantryman received a tangential shot on the left side of the forehead. He arrived at the hospital exhausted, "dried out," unable to swallow. Highly offensive cerebral tissue was escaping from the skull wound. A trephine opening showed that fragments of cranium had been driven into the brain. A curette was used to remove the necrotic brain tissue, whereupon the characteristic odor of gas gangrene at once became apparent. After all debris had been removed a funnel-shaped cavity remained, the lining of which, still infected, was carefully scraped away. The cavity, which was of the size of a small apple, was packed with iodoform gauze. The patient made a remarkable functional rally, and seemed to be out of danger when he suddenly developed fever and mental confusion, and died soon afterward. Section showed that the wound was directed toward the anterior horn of the lateral sinus, but had not reached it. The tamponned area seemed to be in a healthy condition. On the other hand, there was a surprising find on the surface of the brain—a pronounced leptomeningitis, with marked vascularization, the vessels invested with pus, in which a few bubbles were visible. The condition was at its maximum at the margin of the wound, and gradually became less marked as it reached the limit of the leptomeningitis on the occiput.

Insurance Medicine.

THE GENERAL FACTORS DETERMINING MEDICAL SELECTION.

FROM "ALLGEMEINE LEBENSVERSICHERUNGSMEDIZIN"

BY PROF. DR. GEORG FLORSCHÜTZ OF GOTHA.

(*Continued from page* 622.)

The investigation was based upon the total number of losses from tuberculosis which the Gotha Company had suffered up to the end of 1904 among those insured since 1881. These numbered 1,428 cases. Not all, especially among those accepted in the earlier years, furnished data for complete bodily measurements, which explains why in the several measurements the number of cases varies. From the outset all measurements were excluded which had not been obtained by the actual use of the tape and scales at the examination.

Of great importance for the usefulness of the results to be attained was the control measure upon which the investigation was based. The selection was so made that the control subjects were persons who had been accepted for insurance at the same time as those who who had died of tuberculosis. The controls belonged to exactly the same accession and business periods as the tuberculous subjects, and had—especially for the time of admission—the same make-up as the group of tuberculosis decedents. Even the average accession age is, as one would expect, nearly the same; so that even without reckoning the age the comparisons are entirely trustworthy. Cards were used in the investigation, and in order to keep the latter strictly uniform they were selected by myself from 2,856 applications.

Compiling the averages from the tables made we obtain the summary given in Table II. It is shown in the first place that the height (with the exception of the juvenile period, 15-19 and 20-24) is almost the same in both groups; that the chest measure of the tuberculous subjects is notably behind that of the controls, and the waist measure and weight still more so (with the exception of the youthful period, 15-19 and 20-24).

In the second place, the difference between the two groups is the more considerable the higher the age of the risks at the time of insurance. The group which died of tuberculosis were, upon their acceptance for insurance—according to their measurements (in other words their constitution)—essentially inferior to the group of controls.

Let us now omit for the time any further conclusions, and endeavor first to understand the striking relationship between the youthful and higher ages. Are the adherents of the pure contagion doctrine of tuberculosis right when they regard constitutional inferiority not as a cooperative cause of the later disease but only as a consequence of the existing malady; and have we been actually insuring those of ages twenty-five and after who were already sick, while those of ages under twenty-five were still free from disease? It is impossible, for all have submitted to the same selection, and certainly not one has been insured who was in the least infected with tuberculosis.

Assuming, however, that the impossible happens, then must it be demonstrable in figures if we analyze the ages from twenty-five up according to the duration of insurance. For then the first insurance years must in their constitution values be differentiated quite considerably from the following, in which the duration of tuberculosis may be limited merely to months or a few years; because with the briefness of the expired time between the entrance examination and the death the *habitus phthisicus* must have asserted itself in its most severe form; while the latter in those insured for twelve years and upward cannot have come in evidence at all upon acceptance, so that the measurement values must have been the same as those of healthy controls.

(*To be continued.*)

Failure to Disclose Disease Arising Between Application and Delivery of Policy.—An applicant for a life insurance policy in his application answered "No" to questions whether he had ever been afflicted with renal colic. He had in fact, however, suffered from one or more attacks of renal colic prior to the date of the application, and, between the date of the application and the date of the delivery of the policy, he was seized with an attack of renal colic which persisted through several days, and was informed by his physician as to the nature of the disease. In an action on the policy it was held that it was the duty of the insured to have disclosed such illness to the defendant prior to the delivery of the policy, and his failure to do so constituted such fraud as would avoid the policy. "The authorities," the court said, citing the cases, "almost without exception are in agreement upon the doctrine that an applicant for such a policy must use due diligence to communicate to the proposing insurer facts materially affecting the risk, which arise after his application has been made and before the contract has been consummated by delivery."—Harris v. Security Mut. Life Ins. Co., Tennessee Supreme Court, 170 S. W. 474.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

109th Annual Meeting, Held in Buffalo, April 26 29, 1915.

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES

Monday, April 26—First Day.

The PRESIDENT, Dr. GROVER W. WENDE of BUFFALO, IN THE CHAIR.

Address of the President.—Dr. GROVER W. WENDE of Buffalo, after thanking the officers and committees of the Society for their support of his administration during the past year, suggested that it would subserve the best interests of the society if the retiring president, who during his term of office acquired a knowledge of the affairs of the society, were retained in an advisory capacity. He recommended that the constitution be amended so that the retiring president should become a member of the council for one year. In view of the deficit in the treasury during the past year when there had been no unusual or emergency expenditures, and of the fact that such an annual deficit was bound to occur unless their financial policies were changed, and since the three expenditures, Malpractice Defense, the *Journal*, and the Directory, were approximately about 75 per cent. of the total, he recommended that a referendum of the following question be decided by a vote of the membership at large: "Shall the Medical Society of the State of New York continue or discontinue its expenditures for Malpractice Defense, publication of the *Journal*, and publication of the Directory?" In speaking of the scientific work of the society, Dr. Wende said that the wisdom of the reorganization of this part of the society's activities had been amply demonstrated. He expressed regret that the Section on Public Health and Preventive Medicine had been allowed to fall into "innocuous desuetude" and recommended the establishment of a Section on Public Health which would become a clearing house for the critical consideration of all questions bearing upon State as well as preventive medicine; it would exercise a watch over the enthusiasm of public health officials, while at the same time supporting them in their duties. He recommended that this section be known as Section on Public Health, Hygiene, and Sanitation. This year a Section on Syphilis had been inaugurated to emphasize conspicuously the great importance of this disease to humanity, to the profession, and to the State and to establish a precedent for the guidance of other associations in its consideration. A large part of the consideration of syphilis should come within the purview of the Section on Public Health, Hygiene, and Sanitation, as next to the highest expenditure of State funds, which proper preventive medicine could greatly diminish, was the maintenance in institutions of inmates suffering from the effects of syphilis. In view of the ravages wrought by syphilis and in recognition of the inadequacy of existing facilities for checking its dissemination, he recommended the establishment of a system of confidential notification of all cases of syphilis for statistical purposes and the making of arrangements for the diagnosis and treatment by boards of health of all cases of syphilis for which no other provision could be made.

A very instructive course of illustrated lectures had been prepared for the public on much discussed medical questions of the day to be given by eminent authorities on the special subjects chosen. By thus putting the weight of its authority upon the right enlightenment of the people on questions involving preventive and State medicine, this society would protect the public from the evils of ignorance, superstition, and charlatanry, would prove the altruism of the profession, and would create a better understanding by the people of the rational treatment of disease as practised by their profession. He recommended that such a public educational course be made a permanent feature of the annual meetings of the Medical Society of the State of New York.

In speaking on the subject of membership, Dr. Wende said the society should ever keep in mind the fulfilment of that high purpose of the constitution—"to federate and bring into one compact organization the medical profession of the State of New York." After discussing the conditions, all of which might be grouped under illiberality and indifference, which were interfering with the increase in membership of the society, he recommended that a committee of three be appointed to prepare a more exact and clear definition of what should constitute eligibility to membership for the instruction and guidance of the county societies, and to outline some feasible plan for more rapidly increasing their membership.

During the past year the onslaughts of the "antis" and the irregular practitioners upon the legal defenses of the health and physical welfare of the people now on the statute books of the State, had been as many if not more than usual; but with this difference, that they had been pushed with greater vigor and had fallen just short of victory. A communication was early posted to the officers of the county societies which contained a carefully prepared statement of the dangerous pass to which these attacks had come and which made an earnest appeal for prompt and vigorous action. The very indifferent results that followed proved conclusively that something was radically wrong with the methods pursued in regard to legislative matters by both the State and county societies. It was indubitably shown that many of the county standing committees on legislation were simply standing soundly asleep or else had eased their consciences of responsibility by passing the contest up to the State committee. It was evident that a radical change be made in the present method of securing and influencing legislation. The indifference of the members of this society stood in sharp contrast to the efficient organization and enthusiasm of the representatives of the various sects. It had been borne in upon him that the frequent avoidance of defeat was due to the enthusiastic efficiency of the capable chairman of the State committee on legislation. In view of the fact that the legal protection of the health and welfare of the people would never be free from attack so long as there was an annual change of political complexion in the State Legislature, and since the State society in itself had assumed the office of guardian of public health he suggested the following: the creation of a State council on legislation which would act in an advisory capacity to the State committee on legislation and which should consist of the chairman of the State committee on legislation and the chairman of each of the county committees on legislation. They should employ a highly capable man, not necessarily a physician, to be known and to act as secretary to the State committee and the State council on legislation. Dr. Wende recommended that a committee of five be appointed to consider the above suggestion and such other suggestions as had been made or might be made, and to report therefrom a comprehensive plan for consistent attitude and approach on all medical legislation.

With reference to public health administration, Dr. Wende said that by securing the enactment of favorable laws enlarging the duties of departments of public health and granting them autocratic powers without checks of any kind, the profession was aiding in the gradual upbuilding of a powerful centralized organization. However capable the physician at the head, these laws placed inherent human weakness at the mercy of all kinds of destructive pressure by all kinds of ignorance that for the time being had popular support. It seemed that some method must be devised whereby this unwholesome trend must be checked. It seemed, therefore, that in consideration of the necessity for centralized autocratic power and the danger necessarily attendant upon the residence of such power in one individual, this society in conjunction with other legally recognized State medical societies should act as a watch dog over the official acts of such a dictator to protect him in right action and to condemn and prevent wrong action on his part. To this end he recommended that the duties of the committee on public health be so enlarged that it should cooperate with other legally recognized State medical societies in the consideration of the acts of the Commissioner of Health of the State of New York.

Dr. Wende reviewed the subject of Workmen's Compensation, speaking more particularly with reference to the fee-bill, and said that considering that one of the objects of the Society was "to protect its members from imposition," and considering the vast importance of this and like economic questions and the present inertia of the membership and its unjust criticism of those who had failed to "stem the tide" it was imperative to find some other way of handling such questions, and he therefore recommended that a standing committee con-

sisting of five members be created to be known as the Committee on Economics .hat should be on the watch for the appearance of any movement affecting the economic life of the membership, that should at once begin an investigation when such a movement was discovered, and that should report its findings and make recommendations to the House of Delegates at least annually.

A committee had been appointed by the House of Delegates at the last annual meeting to be present at the Constitutional Convention for the revision of the Constitution of the State of New York, and thereat to proffer advice and suggestions upon all such matters of public health and medical practice as might come before the convention. One serious danger possible at this convention was that zealous regulars and fanatical irregulars would endeavor to have written into the fundamental law of the State, provisions governing medical matters that would render them almost as unchangeable as adamant and that in the long run would work mischief to the State, the individual, and the profession. It was Dr. Wende's opinion that regulation of public health and medical practice should be left to the police powers of the Legislature so that all those laws grouped under the "Public Health Law" might have a mobility impossible under constitutional provision.

The speaker called attention to the drawbacks of the present system of State licensure and reciprocity and urged a license to practice medicine that should be nation-wide in its grant. He also endorsed the plan presented at the American Medical Association Council meeting last February for the reexamination every five years of all physicians in practice. Such a procedure would eliminate fossilization and promote advancement in the profession; it would check the aspirations and conduct of irregular practitioners; on the part of the people it would inspire loyalty and confidence and renew their interest. The sole object of such a reexamination would be to prove fitness to practise. Such a plan would make unnecessary the further increase in the requirements of those preparing to enter the profession, and would quickly eliminate any undesirable practitioners while not putting prohibitive restrictions upon ability. The trend of reexamination would be to bring diagnosis to the front as the most important professional attainment, and to relegate to the background the cure of disease upon which the irregulars placed so much stress and upon which their vicious hold upon the public entirely depended. The President recommended that this matter as well as the question of the advisability of adding a fifth year to be spent in hospital work to undergraduate requirements be referred to the Committee on Medical Research for consideration. The continuance of the investigations of the Committee on Midwives was recommended. In addition it was suggested that the Committee on Medical Research should be asked to consider the necessity for aiding the State Department of Health in educating and training would-be public health officers. Finally, Dr. Wende recommended that the functions of the Committee on Medical Research be enlarged and that it be known as the Committee on Medical Education.

Discussion of the President's Recommendations.—The House of Delegates adopted the first recommendation by making the President a member of the Council of the Society. After a lengthy discussion as to the relative values of the Malpractice Defense, the *Journal*, and the Directory, and explanations with reference to the financial status of the Society which showed that the apparent deficit was due to bad debts, some of which had been collected and that in reality the Society had assets amounting to about $9,000, it was decided that it was unnecessary to submit the proposed referendum to the members of the Society for a vote. The recommendation with reference to the notification of all cases of syphilis was adopted, but the one recommending the treatment of cases for which no other provision could be made by boards of health was defeated. It was pointed out that the State Board of Health now made provision for making Wassermann tests. The other recommendations were adopted with the exception of those requiring a change in the By-Laws which were permitted to take the usual course.

Report of the Secretary.—Dr. WISNER R. TOWNSEND presented this report which showed that the membership of the Society had increased by 382 in 1914, which was a larger increase than during any previous year. The total number of physicians in the State was 14,114 on October 1, 1914, while the membership of the State Society on January 1, 1915, was 7,621. Renewed and continued efforts were necessary in every county to increase the membership, but care should be exercised that no undesirable men were admitted. The argument that such men could be better controlled when members than when non-members did not always work out well in practice. The time was not far distant when the majority of the profession as represented by the County and State Societies must take steps to control the conduct of non-members as well as of members. This was an important and delicate question, but one that should be given serious thought, because the public did not discriminate between members of the State Society and non-members but considered all physicians as part of the profession. In the legal profession, the Bar Association, which corresponded with the State Medical Society, investigated complaints against non-members and, if they were found guilty, referred them to the Appellate Division for Punishment. If the State Society were to undertake the investigation of non-members when a complaint was made, it might refer all questions of discipline to the State Board of Regents, who by law had the right to suspend or revoke licenses to practise for various offenses.

The clerical work of the office had greatly increased during the past year owing to the many attempts to break down the medical laws in regard to the practice of medicine, antivivisection, antivaccination, etc. The Committee on Legislation sent out over 10,000 letters, and hundreds of telephone messages and telegrams had been sent and received. On this account it seemed desirable to increase the Committee on Legislation, so that it would have more representatives throughout the State. The District Branch presidents and the councilors might be added as actual members of the committee. The County Society committees could be placed in charge of the District Branch presidents and this enlarged body would be organized for effective work. This report also called attention to the distinct improvement in the work of the County Society officers and to the value of the scientific work of the District Branches and County Societies.

Report of the Treasurer.—Dr. ALEXANDER LAMBERT presented this report containing the certified balance sheets showing the receipts and expenditures for the year 1914 and the bank balances for the past nine years which showed an excess of income for that period of $5,086. The year 1914 showed a loss of $759, which was nearly all due to the large amount of doubtful debts charged off in 1914. A considerable part of this would probably be paid during the current year. The Committee on Publication had already made arrangements to reduce the expense of the *Journal* and the Directory for 1915. These economies together with the increase in revenue from dues, which was estimated at $1,000 for 1915, would probably provide for a satisfactory surplus at the end of the year.

Report of Committee on Publication.—This committee, of which Dr. Floyd M. Crandall was chairman, reported that the regular monthly issue of the *Journal* was 8,500 copies, an increase of 200 per month over the preceding year. During the year the revenue from advertising had been materially increased by the assistance of the Cooperative Advertising Bureau of the American Medical Association. In order to reduce the cost of publishing the Medical Directory the committee recommended that in the 1915 edition all society data excepting the County, State, and National Societies, Societies of Specialists, Academies of Medicine, and Hospital and Alumni Associations be omitted; that the data of the Board of Health of New York City be abbreviated and that a less expensive cover be used.

Report of Committee on the Regulation of the Introduction of Medical Expert Testimony.—Dr. DWIGHT H. MURRAY reported that owing to conditions in last year's Legislature they had not deemed it wise to present a bill. This year they had introduced a bill which had passed both houses of the Legislature and had been signed by the Governor. This bill, Dr. Murray said, was not so farreaching as it should be; it covered criminal cases only, but it was an entering wedge and they hoped to get some changes in the Constitution of the State at the convention now in session.

Report of Committee on Public Health.—Dr. JOHN M. VANCOTT of Brooklyn presented this report, in which he stated that the only important communications which the committee had received during the past year was one from the Committee on Public Health of the State Legislature, entitled "An Act to Amend the Public Health Law, Relating to the Practice of Medicine," and one from the New York Committee for the Pre-

vention of Blindness asking the endorsement of the Medical Society of the State of New York to resolutions approving the contemplated action of the State Department of Health to have all cases of redness or swelling or discharge from the eyes of newborn infants reported promptly in such a way as to secure adequate medical treatment for cases not in the care of physicians, or such assistance from the health officer in the shape of nursing, or consultation or laboratory investigation, as the attending physician might desire. In order to further the efforts of the State Department of Health and the New York Committee for the Prevention of Blindness to extend in New York State an educational campaign among laymen for the conservation of vision, they suggested that the Medical Society of the State of New York recommend to the Public Health Council of the New York Department of Health that it declare suppurative conjunctivitis a reportable disease as well as ophthalmia neonatorum. This report further stated that the committee could not agree with the attitude of the Commissioner of Health of the State in opposing the compulsory vaccination of children in the public schools. They deplored any act that looked toward letting down the bars with reference to compulsory vaccination. The opinion was expressed that there was reason to believe that the United States would be menaced with cholera and other highly communicable diseases after the European War ceased, and it was to be hoped that the Governor and all others in authority would be liberal in granting to the Quarantine Station such appropriation of moneys as might be necessary in the judgment of the health officer of the port of New York. They reiterated the opinion expressed in a former report that the Quarantine Station should remain a State and not become a Federal institution. Though they considered it difficult to form a reliable opinion as to the operation of the new drug laws, they believed that with proper amendments, which time and experience would suggest, they would prove rather beneficial than otherwise.

Report of Committee on Legislation.—Dr. Louis K. Neff reported for this committee, reviewing the bills which had been introduced into the Legislature which did not become laws. These bills were mostly designed to further the interests of irregular practitioners, to do away with compulsory vaccination and with vivisection.

Report of the Committee on Midwives.—Dr. John Van Doren Young reported for this committee, stating that four meetings had been held and that they had endeavored to get as much information as possible by correspondence. The scope and importance of the work had grown until the committee had realized that before any complete and exhaustive study with the necessary recommendations could be made, it would require two or more years' work. It would be desirable to have a committee such as the present one made a more or less permanent feature of the society's work. In taking up this work the committee had found that the problem could best be studied under two heads, that of New York State and of New York City. There were five times as many midwives in New York City as in the balance of the State. There were 1,448 midwives registered in New York City, who delivered last year 52,997 children. The midwives were delivering more than four times as many women as the entire capacity of the lying-in hospitals of the city. Outside of New York City the midwives practised without any definite control such as was exercised by the Board of Health over those practising in the city. The committee believed that at the present time it was impracticable to abolish the midwife and that the problem, therefore, resolved itself into educating and improving her so that her work would be of such a character as at least partially to excuse her existence. It was the belief of this committee that the midwife practised medicine, and in so doing violated the Medical Practice Act of the General Public Health Law. The first effort of the State Board of Health to face this problem was by bringing out Chapter 4 of the Sanitary Code relative to the registration of midwives January 1, 1915. The committee at first believed the requirements too low, but were now convinced that this was a step in the right direction and would eventually be productive of great good by giving the State Board of Health the knowledge of the existence of the midwife and her field of labor, and thus enabling them in the future better to control the situation.

Report of Committee on Medical Education.—Dr. William Francis Campbell presented this report, in which the opinion was expressed that the standard of preliminary education for the study of medicine should be raised so as to conform to the standard adopted by the Council on Medical Education of the American Medical Association. While a minority of the committee felt that the ideal standard would be a preliminary requirement of two years of collegiate work in addition to four years' high school education, the majority maintained what was immediately desirable was to urge the State Board of Regents to adopt as a standard of preliminary work one year of collegiate work, including courses in physics, chemistry, biology, and a modern language, preferably French or German, in addition to a four-year high school education. The subjects upon which the State demanded examination should be as follows: Anatomy, Physiology, Chemistry, Bacteriology and Pathology, Hygiene and Preventive Medicine, Obstetrics, Surgery, and Internal Medicine, excepting therapeutics. The character of the examinations of candidates seeking the license to practise medicine encouraged the quiz cramming methods and discounted real knowledge of how to make a clinical examination and arrive at a diagnosis. The Regents should require practical laboratory and clinical tests. The committee recommended that the Regents of the State of New York require that every person who was to enter the practice of medicine after a certain date should have taken at least one year as an interne in a hospital registered by the Regents of the State of New York as meeting its standards for teaching hospitals. In closing it was urged that in view of the efforts made each year at Albany to secure special legislation which tended to impair their medical educational standards, they should insist that the same educational standards apply to all no matter what therapeutic measures were used in the treatment of disease.

Report of the Workmen's Compensation Committee.—Dr. Alexander Lambert presented a lengthy report of the activities of this committee, relating the method by which they had arrived at what they considered suitable remuneration for services rendered under the Workmen's Compensation Law. By meeting with the representatives of insurance companies and by coming to an agreement with them on this fee bill the committee had succeeded in raising the fees paid to the profession in three-fourths of the cases coming under the Workmen's Compensation Law over that which would have been paid without the agreement between the committee of the Medical Society and the insurance companies. It had prevented the possibility of various corporations doing insurance work underbidding one doctor against another. It had placed the organized profession in the State in a dignified position of agreement and cooperation with those who were endeavoring to put into force a new social law and social condition. It was stated that the committee was aware of the vast amount of criticism and discussion which the question of a proper fee bill had raised and explained its reasons for believing that the Workmen's Compensation Law would bring about a fairer return for work done in hospitals than was at present given to physicians and surgeons and would bring about the correction of many abuses which had grown up in this connection, and on the whole physicians, as a class, would receive more than they were at present receiving for this class of cases. They considered one part of the bill as objectionable, and that was the flat rate for first aid operation and full treatment, which comprised the first column of the charges under the fee bill. They believed that this flat rate should be abolished. The committee believed that the economic questions involving the medical profession under this law were of such importance to the profession that the State Society should have a special committee to interest itself in them.

Report of Committee on Medical Research.—Dr. Frank Van Fleet reported for this committee that certain bills had been introduced into the Legislature to regulate animal experimentation which had been referred to the Committee on Judiciary of the Senate and Assembly and were not reported out of committee.

Report of the Counsel.—James Taylor Lewis presented this report in which he gave an outline of the actions brought during the past year. They were fewer than during the previous year and more had been disposed of. It was the belief of the counsel that the number of private settlements by doctors had now been reduced to such a small percentage as to justify the belief that practically all members of the State Society rested confidently upon the efforts of the Malpractice

Defense of the State Society in cases in which negligence was charged against them. During the past year many physicians who were defended by insurance companies had called upon the counsel of the Society for help, and it was very interesting to note that in all these instances the insurance companies were only too glad to stand aside and permit the counsel of the Society to conduct the case. This, however, did not remove the danger of a policy. It was time that the House of Delegates took some affirmative action in order that the insurance companies who reaped the benefits should not be permitted to make use of the State Society to pull their chestnuts out of the fire. This should be stopped at once. No member of the State Society who wanted to be insured against his negligence should be defended by the counsel of the Society. Members of this great profession should not place themselves in the position of seeking indemnity against their own carelessness; it should be, by statute, made unlawful. Mr. Lewis said that he felt sure that the number of cases brought might be largely diminished if the importance of abandoning their insurance and relying upon their own resources could be sufficiently impressed upon the minds of the various members. For the protection of the professional standing of its members the House of Delegates should take some definite action in this matter.

These reports were all adopted by the House of Delegates after certain amendments had been made. After considerable discussion the report of the Committee on Public Health was adopted with the exception of that part recommending the Quarantine Station at the Port of New York should remain a State and not become a federal institution, which section was disapproved. The report of the Committee on Medical Education was adopted with the exception of the recommendation requiring a fifth year as a hospital interne. It was shown that this recommendation was not practicable at the present time since hospitals were not standardized in this State and there were insufficient places to accommodate all graduates in medicine. The report of the Workmen's Compensation Committee was adopted with the request that the committee should not formulate a fee bill, since there was danger that insurance companies would take the minimum bill as the maximum and thus do physicians a great injustice.

Tuesday, April 27—Second Day.

Election of Officers.—The following officers were elected for the coming year: *President*, Dr. W. Staunton Gleason of Newburgh; *First Vice-President*, Dr. Montgomery E. Leary of Rochester; *Second Vice-President*, Dr. H. L. Winter of Cornwall; *Third Vice-President*, Dr. Thomas McKee of Buffalo; *Secretary*, Dr. Wisner R. Townsend of New York; *Treasurer*, Dr. Alexander Lambert of New York; *Chairman of Committee on Scientific Work*, Dr. Thomas J. Harris of New York; *Chairman of Committee on Public Health*, Dr. Joshua M. Van Cott of Brooklyn; *Chairman of Committee on Legislation*, Dr. James F. Rooney of Albany; *Chairman of Committee on Medical Research*, Dr. Frank Van Fleet of New York. The *Committee on Prize Essays*, consisting of Dr. A. Vander Veer, Dr. John F. W. Whitbeck, and Dr. Edward D. Fisher was continued.

The following were appointed Delegates to the American Medical Association for two years: Dr. Grover W. Wende of Buffalo, Dr. William Francis Campbell of Brooklyn, Dr. Edgar A. Vander Veer of Albany, Dr. Henry L. Elsner of Syracuse, Dr. Floyd M. Crandall of New York, and Dr. John O. Polak of Brooklyn; *Alternates:* Dr. W. E. Bowen of Rochester, Dr. W. D. Ludlum of Brooklyn, Dr. Elias H. Bartley of Brooklyn, Dr. J. R. Kevin of Brooklyn, Dr. J. W. Draper of New York, and Dr. G. A. Peck of New Rochelle.

Saratoga Springs was chosen as the place of meeting next year. The time of meeting was referred to the Council, to be announced later.

Shall the American Medical Association Have Appellate Jurisdiction?—Dr. Wisner R. Townsend read a telegram from the headquarters of the American Medical Association asking that the State Society take action on the proposal made at the last meeting of the American Medical Association that the Judicial Council of the American Medical Association have appellate jurisdiction in differences between members of different county societies, between different county societies, between a county and State society. This simply meant that in case of local differences there would be a court of appeal, as it were. After a discussion of this matter, it was decided that as the proposition now stood it was too indefinite; it did not state whether such jurisdiction applied to matters of fact or matters of procedure. It was the opinion of the House of Delegates that the State Society should be the unit and that it should be able to manage differences that might come up without help from an outside source.

Section on Syphilis Discontinued.—It was voted to discontinue the Section on Syphilis; the work of that section was to be under the new Section of Public Health, Hygiene, and Sanitation. The other sections would be retained as they were now organized.

GENERAL SESSION.

Tuesday, April 27, 1915.

The President, Dr. Grover W. Wende, in the Chair.

Invocation.—The one hundred and ninth annual meeting of the Society of the State of New York was opened by prayer by Rabbi J. Kopald.

Addresses of Welcome.—Dr. Albert T. Lytle of Buffalo, Chairman of the Committee on Arrangements, welcomed the guests in behalf of the medical profession of Buffalo and told of the provisions made for the entertainment of the visiting physicians, calling especial attention to the excellent exhibit which had been assembled and the popular lectures on health subjects which were to be given. He urged that these might become a permanent feature of the meetings.

Mr. Herbert A. Meldrum, President of the Chamber of Commerce of Buffalo, said that it had once been believed that competition was the life of trade, but they had gradually learned that liberal cooperation and not cut-throat competition was the secret of success in business. The same thing was true in medicine; it was by cooperation that they would overcome disease. As health was the most important factor in life and they were here to promote it, he felt that they should be encouraged. Buffalo was a popular convention city, but none came here to which he gave greater honor than to the Medical Society of the State of New York.

Oration on Medicine.—Dr. Victor C. Vaughan of Ann Arbor, Mich., President of the American Medical Association, delivered this address. He explained that the Editor of the *Journal* had not returned his manuscript, so that when they read his address if they found that it did not exactly correspond with his remarks this would account for any discrepancies. Dr. Vaughan said that his recent work somewhat upset their preconceived notions of infection and immunity, and while it was all very interesting he was not prepared to say exactly what practical value it might have in medicine. First, they had all been taught that bacteria were microscopic plants. So far as his work was concerned, this was not true; bacteria were not plants and the reason was easy to explain. The early workers found bacteria, especially anthrax bacilli, not readily soluble in dilute acids or alkalies, and, therefore, said they were vegetable organisms. This error had been repeated until the present time. It should be remembered that horns, skin, hair, and teeth were not vegetable substances, and yet they were not soluble in dilute acids or alkalies. The thing that determined whether a substance was plant or animal was the presence or absence of cellulose in the structure. If there was no cellulose substance present the thing in question was not a plant. It did not follow since they could not say that bacteria were not plants that it could be said that they were animals. They would simply say they were bacteria. Plants gave off oxygen and took in carbon dioxide, while animals took in oxygen and gave off carbon dioxide. Now it was found that bacteria took in more oxygen than they gave off in carbon dioxide, thus there was an excess of oxygen, which indicated nitrogen metabolism. The bacterial cell had a direct nitrogen metalobilsm just as our bodies had. Another question that was of great import was whether the bacteria were nucleated or not. Most bacteriologists had said that bacteria were not nucleated, because they showed no difference in staining, but they did show nuclear staining; he did not specify that the capsule or flagellæ or extraneous substances connected with the bacteria showed the nuclear tissue, but chemical analysis showed nuclear acid, and a carbohydrate group had been identified, showing that bacteria were nuclear tissue. This was important because the chief function of nuclear tissue was to grow and to multiply. Bacteria were as-

similated by the body because they were simple in structure, but in chemical composition they were just as complex and highly organized as the most highly developed cells in the human body. Hence infection did not mean a contest between unequal combatants but a contest among equals. With this understanding with reference to the structure of bacteria they might consider the mechanism of infection and immunity. Whether or not a given bacteria was pathogenic depended on two things. Before one could have any infection there must be a living thing to cause the infection; one could not get infection with arsenic or strychnine, but one could have poisoning. Again the bacteria must live on the animals which were infected, and must not only live but must multiply. Bacteria carried on the surface of the body did not infect. It was estimated that 70 per cent. of the people coming in contact with cases of meningitis carried the meningococcus, but they were not infected with the clinical disease. In a school, where there was an outbreak of diphtheria, it was found that 30 per cent. of the children were diphtheria carriers but they did not all develop diphtheria. Before one could have infection the organisms must grow and multiply. In order that they might grow they must feed on proteids in the animal body. All bacteria had resting stages, not only those that showed spore formation, but in his opinion they must have resting stages even if they did not form spores; for instance, the Shiga bacteria of dysentery, especially in the dry state, did not form spores, but they broke into granules and under appropriate conditions these came to life. All living things must eat and they ate what was in reach and, further, they ate what they could break up and utilize. A substance might be rich in proteid, but if it could not be digested it did not promote growth. The great majority of bacteria were not able to live on the human body and hence were not pathogenic. This also helped to explain the selective activity of bacteria. Again, if the body cells digested the bacteria they were all killed and there was no infection. Bacteria were pathogenic when they could eat body proteins and formed digestive ferments which the body cells could not destroy. One found that in typhoid fever, for instance, no symptoms manifested themselves until six or ten days after the bacilli had been ingested. During this time the host was in good health, but this was the time when the bacteria were growing and multiplying most rapidly; hence it was not the direct growth and multiplication of the bacteria that caused the symptoms of disease. Yet this period was most important and the outcome of the infection depended on what happened during this period. During this period this organism furnished a ferment; and by a synthetical process the soluble proteid was converted into a cellular proteid, that was, simple proteids were combined into complex ones. No poison was liberated, and hence there were no symptoms. During this period normal proteids were converted into foreign proteids. At the end of the incubation period, which need not necessarily be a sharply defined one, when symptoms began the thing that had happened was that the body cells had learned how to combat the invader, first with the phagocytes and then with every living cell. Metchnikoff claimed that the phagocytes only ate the bacteria, and while they owed so much to his investigations they had now learned that not only did the white blood corpuscles eat the bacteria but that all living cells did the same. The body cell having once developed the function of digesting the invading organism in the process of resolving cellular to soluble and complex to simple substances poisons were set free and the symptoms of disease appeared and life was threatened. If this was true, then by the injection of a foreign protein, like egg albumen, in varying doses and at varying intervals, they ought to be able to produce any kind of a fever they wanted to, an acute fever or a fever resembling typhoid. This they had been able to do, reproducing the symptoms of that disease even the morning recession and the afternoon exacerbation of fever. This showed that the fever and the lesions were due to the parenteral digestion of protein. It was the destruction of the protein ferments that caused the symptoms of disease. To be protected against any disease the body cells must be trained beforehand to digest the ferments. In vaccination the body cells were trained beforehand to digest smallpox virus, and hence when that virus got into the body it was destroyed immediately, and the person was said to be immunized against smallpox. It was a misfortune to suddenly develop the power of digestion during an infection so that the poisons were set free too abundantly. In certain infectious disease the death rate was higher among the stronger and more robust than among the comparatively weak and infirm. Dr. Vaughan said he thought he had made a discovery when he found this out independently, but after reading he found that this fact was recognized in the past. The introduction of bleeding as a treatment for fever had its foundation on the observation that more patients recovered after having hemorrhage than when they did not have it. The observation that the strong perished and the weaker frequently survived was noticed by Thucydides in reference to the plague, typhus fever, and perhaps other diseases. A description in the sixteenth or seventeenth century by Cogan described an epidemic of typhus thus, "so it went through the country picking out the handsomest, the lustiest, the best, just as you would go through a flock of sheep and pick out the best." Even Herbert Spencer was wrong when he stated that disease was a good thing in that it killed off the unfit. This might not be true of all infectious diseases, but it probably was true of those in which the combat was waged chiefly by the phagocytes. The cellular substance to which an animal was highly immune killed the animal on the first injection, provided the injection was large enough. The animal with this high immunity split up a very large amount so rapidly that the poison was overwhelming and killed the animal. A non-pathogenic organism injected in sufficiently large quantity would kill speedily. The same thing applied to all vaccines; no vaccine gave complete immunity, but only a relative immunity. The most complete immunity conferred in any disease was that in yellow fever; this was probably because yellow fever infection was carried by the mosquito and one mosquito could not carry a large amount of the infection. In closing Dr. Vaughan said he believed in giving credit where credit was due and that a Spanish physician, named Ferran, had vaccinated against cholera in the nineteenth century and had received nothing but abuse.

SECTION ON PEDIATRICS.

Tuesday, April 27—First Day.

DR. JOSEPH ROBY OF ROCHESTER, IN THE CHAIR.

Hydrocephalus—Later Experiences in Its Treatment by Cisterna Drainage.—Dr. IRVING S. HAYNES of New York presented this communication in which he referred to the procedures of Gaertner and Thayer for securing drainage in cases of hydrocephalus, but did not consider them as practical as the operation which he had devised. He stated that the injection of phenosulphonaphthalein provided a means of determining something in reference to the type of case with which one was dealing and whether operation promised hope for alleviation of the condition, and also the type of operation to be performed. He had operated on 12 cases all but two of which were totally blind. He stated that the only logical means of draining the Cisterna was into the blood stream. This he effected by means of a silver cannula with a short arm and a long arm at right angles with each other. Dr. Haynes demonstrated by means of lantern slides the way in which the tube was inserted from the Cisterna Magna to the sinus into which it was desired to drain the fluid. He also showed simple apparatus to be attached to a table for supporting the head of the patient during the operation. While he had been able by this method to effect drainage and in some cases to somewhat improve the contour of the child's head and to prolong life he was by no means enthusiastic, because there seemed to be little or no improvement in the mental or physical condition of these children.

Dr. GODFREY R. PISEK of New York, said he was not so pessimistic with reference to this operation as was Dr. Haynes. He thought they had learned something worth while. They had learned that there were certain types of hydrocephalus, some operable and others not. It must be forgotten that these were surgical experiments; the cases that he had sent to Dr. Haynes were absolutely hopeless. If they had taken these cases early, made the phenosulphonaphthalein test, and employed the type of drainage that seemed indicated, the results might have been better. If they got the child before he was damaged mentally, or after an attack of acute meningitis when hydrocephalus developed as a complication, this operation might offer hope of accomplishing something. The technique was not simple

and required a surgeon skilled in brain surgery. There was a type of cases in which the fundus of the eye showed no changes, and though there were signs of increased cranial pressure the tests showed that with a pervious foramina it would be a satisfaction to feel that there was a method of treatment that promised something, that they were not absolutely hopeless. Dr. Pisek referred to several cases of hydrocephalus in young infants that responded to lumbar puncture repeated at first after two weeks, then after three and then after six.

Dr. CHARLES W. HENNINGTON of Rochester said that Dr. Haynes' operation seemed to be in line with what they had found in laboratory work in hydrocephalus. Cuchman in his pathological studies showed the absorption of the tufts and villi into the longitudinal and other sinuses. It seemed that in this operation they might have the solution of the problem as to whether the dura and arachnoid should be punctured from the reverse side. He agreed with Dr. Pisek that if these cases were brought early for treatment and the phenosulphonaphthalein test employed to determine the type of obstruction they might get some good results.

Dr. HAYNES said the phenosulphonaphthal in tests for this purpose had come out since he had been doing this work and he had not had the opportunity to test them. He thought the suggestion made Dr. Hennington would give relief when the obstruction was above the aqueduct of Sylvius. This was suggestive since all attempts at anastomosing veins in the brain had been unsuccessful. The technique would be easy. The end of a rubber tube could be thrust into the ventricle and the other into the laterial sinus. Dr. Haynes said he had gone into this work with enthusiasm but the paucity of results had been discouraging and he was glad to hear that they thought this work might lead to something practical.

The Schick Reaction and Its Practical Application.—Dr. ABRAHAM ZINGHER of New York presented this paper, in which he outlined the method of applying the Schick test. He stated that the dose of toxin used was 1/50, the amount required to kill a guinea pig in four days. He emphasized the importance of distinguishing between the true—and the pseudo—reactions. The true reaction left pigmentation and showed superficial scaling, while the pseudo reaction showed more infiltration, but disappeared in a few days while the true reaction lasted considerably longer. It was also necessary to have a standard reliable toxin, the primary dilution being 1/10 in carbolic acid. This would keep for a week or two. If it was too dilute it deteriorated rapidly. Many individuals normally developed antitoxin in their plood and 1/30 of a unit would render the individual immune to diphtheria. The Schick reaction had been carried out in the Willard Parker Hospital in 1,200 cases. Of these 656, or 54 per cent., gave negative reactions. It was not necessary to give diphtheria antitoxin to those who gave the negative reaction. This was the fact that rendered the test so valuable. During the early months of infancy children were comparatively immune but susceptibility increased gradually until between the ages of one and four years 67 per cent. reacted positively. Between the ages of four and six years, 53 per cent. reacted; from six to eight years, 37 per cent. From this time on susceptibility decreased rapidly. It was interesting to note that when an older child in a family reacted positively to the Schick test the younger children were also positive reactors; this happened so consistently that if one found an older child giving a positive reaction it was not necessary to make the test on the younger children. When they found children who gave positive diphtheria throat cultures and a negative Schick reaction, they assumed that such children were only carriers of diphtheria and did not have the disease. Dr. Zingher also showed some of the results obtained by his experiments with toxin-antitoxin, and spoke of the relative value of intravenous and intramuscular injections of antitoxin, the intravenous injections being much more effective and were indicated in cases of diphtheria that were not treated until the third or fourth day. In those children giving a positive reaction, after the effect of the first immunizing dose of antitoxin was exhausted, then a second dose conferred immunity for from seven to ten days only.

The Treatment of Scarlet Fever with Convalescent Blood.—Dr. ABRAHAM ZINGHER of New York presented this paper. (See MEDICAL RECORD, Report of Section on Pediatrics, N. Y. Academy of Medicine, February meeting.)

Results of the Schick Test at the Rochester Orphan Asylum.—Dr. STEARNS S. BULLEN of Rochester reported the results of the Schick test in about 140 children in this institution, which was conducted on the cottage plan. In May, 1914, 132 children were tested. One hundred of the same children were tested again in April, 1915. On both occasions the toxin was diluted with normal saline so that the required amount, 1/50 minimum lethal dose for the guinea pig, was contained in 0.2 c.c. At the time of the first test, 56 of this group of children had at least 1/30 unit of natural diphtheria antitoxin per cubic centimeter of serum. The remaining 44 had less than this amount, and would be considered susceptible to diphtheria. Shortly after these tests were made a small supply of toxin-antitoxin mixture was received from the New York Health Department. It was decided to immunize actively the susceptible children. Only those children who showed strong positive reactions were treated. Forty-one such children were given ¼ c.c. of the toxin-antitoxin mixture subcutaneously, on two occasions with a four-day interval. Of this number, 35 were still in the institution in April, 1915, and were again tested. All except 8, 77 per cent., still gave strongly positive reactions, showing that they had developed very little, if any, antitoxin as a result of the treatment. In 100 children who were first tested and still remained in the institution, the test was applied in April, 1915. Of these, 45 showed more or less strongly marked reactions, while 52 gave no reactions. Eighteen who showed positive reactions eleven months before, now showed negative reactions. Included in this number were the eight cases already mentioned as having developed possible immunity as a result of the treatment with the toxin-antitoxin treatment. Of the children who gave negative reactions on the first test, 15 now gave positive reactions. The author said this series of tests was reported not because it was sufficiently large to enable one to draw conclusions, but because it suggested two things. First, that positive or negative results with this test did not give data which remained the same for an indefinite period of time. Secondly, by combining the Schick test and throat cultures, one would be able to single out the carriers. In none of these 235 injections did any bad results occur.

Immunization Against Measles.—Dr. CHARLES HERRMAN read this paper, in which he declared that the number of cases of measles remained as great as ever. It could only be diminished by immunization against the disease. After giving the mortality statistics for this disease he stated that infants under five months of age were relatively immune, and in exceptional cases in which they were infected with the disease it appeared in a mild and atypical form. One attack of measles usually protected for life. The nasal discharge contained the virus twenty-four hours before the appearance of the eruption. Having convinced himself that infants under five months of age were relatively immune, he obtained the consent of a mother to inoculate her infant then four months old. It seemed logical to assume that as the infant at that age was not absolutely immune, direct inoculation would convert a temporary into a more or less permanent immunity. At no time did the child present any evidence of injury and he then proceeded to inoculate others. The material for inoculation was obtained from otherwise healthy children, taken twenty-four hours before the eruption of measles appeared. A small quantity of mucus from the nose was collected on swabs of cotton. Only perfectly healthy infants under five months of age were inoculated. The swab was applied gently to the nasal mucous membrane. Forty infants were thus inoculated. The majority showed no distinct reaction, fifteen had a slight rise of temperature, and in a few instances a number of small spots were noted on the face or body. Of the forty cases, four over one year of age had come in contact with cases of measles and had not contracted the disease. Having satisfied himself that those infants who were inoculated were immune, two of the forty were reinoculated at the age of twenty-one and twenty-three months, respectively, with negative result. It had been shown that the virus of measles was filterable, but he believed that the filtrate could not be depended upon for purposes of inoculation. It would be desirable to devise some method by which the virulence of the infectious mucous material could be retained for more than twenty-four hours.

Pyelitis: Its Clinical Significance.—Dr. EDWARD J. WYNKOOP of Syracuse read this paper, which he said

he presented because pyelitis unrecognized might cause considerable damage. In girls the infection might gain entrance through the urethra more often than in boys, or it might be carried from the intestinal tract. It might occur as a complication of some other conditions or it might be an independent disease. The bladder need not necessarily be infected. The classical symptoms of chill, fever, and pain in the kidneys might not be present. In relapsing cases the chill might not be repeated. In any case with irregular fever, interstinal symptoms, frequent micturition and anemia, it was well to bear in mind the possibility of pyelitis. In examining the urine a twenty-four-hour specimen only should be taken. Symptoms referable to the urinary tract and anemia should always make one suspicious of pyelitis. This was a condition more frequent than they had believed and should be borne in mind as not every illness in children was to be attributed to the intestinal tract. In treating pyelitis the author had found urotropin and potassium citrate valuable; his preference, however, was for the potassium citrate. Plenty of water and attention to hygienic rules were a great help. Vaccines had not proved as effective as had been hoped. The treatment should be persisted in as long as pus was found in the urine, even though the symptoms had disappeared.

Dr. Walter Lester Carr of New York said all were agreed that in most instances pyelitis was an infection of the colon bacillus type, but the peculiarity of the attack required some consideration as it did not always seem to be associated with intestinal disturbances that attracted attention, nor did it always show itself after a colitis of which one could find record. Many of the cases, according to Dr. Carr's experience, were seen after influenza, and yet cultures of the urine showed pure colon infection. Kelly and Burnham believed the common origin of pyelitis was in the blood stream and the ascending infection was rare. While there was a preponderance of cases among females there were more cases among the males than were formerly noted. As the condition in the male could hardly result from an ascending infection, it would be well to study more carefully the influence of the blood stream infection. At this time he believed they were getting satisfactory results in the treatment both by the free use of alkalies and by urotropin, but he was a little in doubt as to the end results in these children. The only way to record them properly was by examination of the urine over a long period. He was suspicious of reinfection or reinvasion. During the acute attack Dr. Carr said he used irrigations and such laxatives as were called for. The elimination of milk from the diet, if there was constipation or foul stools, was most important and the administration of castor oil at such a time was of unquestionable benefit. In closing Dr. Carr urged upon practitioners the more careful routine of examining the urine in infants and young children who had intestinal disturbance, chills, fever, and prostration.

Dr. Pisek of New York said that the principles of the Schick reaction had been well summarized in the paper. Now all were enthusiastic about this test, but they would find that soon the pendulum would swing the other way and the results of the test would be questioned. Improper technique and inferior preparations of toxins would give doubtful results. The tests should not be undertaken by those who had not had contact with the methods used and experience in observing the difference between true and pseudo reactions at first hand. Dr. Zingher's 600 cases were certainly valuable. They would reap some value from this study of the Schick reaction from the fact that the giving of those tremendous doses of antitoxin, thirty to sixty thousand units, would be discouraged.

Dr. Charles Herrman of New York said the Schick reaction had proved itself of great practical value especially in institutions, schools, hospitals, and asylums. They had recently had several cases of diphtheria in the children's ward of the Lebanon Hospital. Cultures from the nose and throat of physicians, nurses, and patients showed that several gave positive cultures. The Schick test was applied and all who gave a positive reaction were immunized. Only those nurses who had a negative reaction were allowed to attend patients. In addition to the value of the reaction in the selection of patients requiring antitoxin it was useful in determining the proper dose of antitoxin and the relative value of the different methods of administration. It was well known that patients having measles were susceptible to diphtheria. This reaction enabled one to pick out the susceptibles who required reinjection. As to the treatment of scarlet fever with convalescent blood, the blood in all probability contained antibodies against the disease. However, it did not necessarily follow that blood which contained sufficient antibodies to protect against future attacks would also have a specific effect upon the disease when it was already present. There was a quantitative difference; the body of a person convalescent from scarlet fever who was immune contained fifteen to twenty times the amount of blood which was injected into the patient with scarlet fever. They knew that sera which had a specific effect were produced in diseases caused by bacilli which developed toxin. They did not even know whether scarlet fever was caused by a microorganism. There was no doubt but that convalescent blood had a distinct and apparently favorable effect upon the temperature. Rees and Jungman and Koch admitted that complications were not prevented, and when they occurred there was a new rise of temperature. In view of the fact that complications were usually due to secondary infection with streptococcus, it would seem logical to combine the convalescent blood with Moser's serum. It appeared that they would not be able to obtain a definite idea of the value of this disease until it could be successfully transmitted to animals.

Dr. Albert D. Kaiser of Rochester said that they had used the Schick test in 300 cases in the Rochester Hospital and no person who gave a negative reaction had contracted diphtheria, but they had had several violent reactions. In one instance the pigmentation had persisted for several months. The Schick reaction had helped them reduce the dosage of antitoxin; in not many cases were they giving more than two or three thousand units. At Dr. Roby's request Dr. Kaiser related that they had in their hospital a child who was vaccinated on Easter Day. Infection took place and the child developed erysipelas. At the same time they had a woman in the hospital who was having a second attack of erysipelas. They had given the child an injection of citrated blood from this patient who was convalescing from her attack. This had been done yesterday and the child seemed to be improving to-day.

SECTION IN SURGERY.

TUESDAY, APRIL 27—*First Day.*

Basal-Celled Epithelioma: A Report of 200 Cases.—Dr. Robert F. Barber of Brooklyn presented this communication. Kronpecker in 1903 was the first to describe basal-celled epithelial tumors. Were recognized to involve salivary glands, the ovaries and the skin. He stated that various types of cells could not be recognized in the tumors. Barber said these constituent cells did not, under morphological and histological study, show "prickles" or epithelial bridges. The neoplasms were called by some adenomata akin to carcinomata. Of the 200 examined by Dr. Barber he states 14 showed epithelial pearls and only 2 epithelial bridges. They were said to spring from the germinal cells of the skin and were described as having different potentials. These were called the cellular potential, evidenced in the various types of tumors, the glandular potential, accounting for the cystic tumors, and the pigment potential, manifested by the pigmented growths. The types were described as (1) simplest—a "nest" of cells in the dermis, (2) alveolar, with a small amount of stroma, (3) scirrhous, with a large amount of stroma, and (4) adenomatous, with glands and cysts. The increase in the connective tissue was interpreted as evidence of inflammation. Previous lesions were called (in those from whom it was elicited), pimples in 44, warts in 5, burn in 1, and the pressure of eyeglasses in 1. The frequency was 100 in men and 100 in women. The age was in the average case 56 years. There were 2 in the third decade and 4 in the fourth decade. The average preoperative duration was 6 years, the greatest being 28 and 25 years respectively, the shortest 6 weeks. The mean size of lesion was 3 cm., the largest 8 cm.; the smallest under 1 cm. The following table of the duration in years of tumors of the various types was submitted: Scirrhous, 1; adenomatous, 12; scirrhous, 12; alveolar scirrhous, 15; alveolar scirrhous, 6; alveolar scirrhous, 18; scirrhous, 14; adenoalveolar, 15; scirrhous, 16; alveolar scirrhous, 2 years. Recurrence followed excision in 16 cases; *x*-ray, 19; cautery, 6; radium, 3; pastes, 17; acid, 2; curettage, 1. Bone was involved in two cases only. The distribution was: Nasal, 70; orbital, 42; cheek, 40; frontal, 19; ear, 14; lip, 4; scalp, 2; 98 per cent. occurred on the head. The

surface form was ulcerated in majority of growths, occasionally elevated as nodules, rarely pedunculated. The elevated and pedunculated forms were prone to cystic degeneration.

Dr. JOHN B. BISSELL of New York ascribed the curative effect of *x*-ray to the tendency to fibrous tissue development in the neoplasms of Dr. Barber.

Dr BARBER in conclusion presented a case with a "slight bump" noticed 7 years ago; grew to a size of a quarter, was refused operation, but finally excised by a Chicago surgeon. It recurred after 1 year and 2 months.

Removal of Cancer by Radium.—Dr. JOSEPH B. BISSELL of New York described cancer destruction by radium. Radium caused hypertrophy of the nucleus and a keratinization of the cytoplasm. The connective tissue became more vascular, and the cells proliferated. He cited a case of twelve years' duration before excision of the breast for carcinoma. There was glandular axillary involvement as well as extension to the other breast following operation. Radium applied, freed the skin from microscopical evidence of cancer. The deeper cells became monstrous. Fibroblasts became numerous. The abnormal cells seemed most susceptible to the rays. They underwent granular degeneration or were absorbed. The infiltration was first leucocytic then round celled in the cases benefited under radium. He reported several cases, including:

CASE I.—J. S., 61 years, with a basal-celled ulcer of 3 in. x 2½ in. Was operated upon twice. Was healed under radium after 1,560 milligram hours.

CASE II.—Orange-sized growth following recurrence from upper sternal region; 2,020 milligram hours caused it disappear.

CASE III.—Case seen in May, 1914. Was nodular and recurred and burned after several applications of radium. Final report after 5,536 milligram hours in April 15 was few "suspicious spots."

CASE IV.—No trace of growth after 1,120 milligram hours.

CASE V.—Sarcoma of lip caused to disappear after 550 milligram hours.

CASE VI.—Epithelioma of ear cured after several applications of radium.

CASE VII.—Spindle-celled sarcoma removed by 320 milligram hours.

CASE VIII.—Epithelioma from floor of mouth removed by 2,600 milligram hours.

CASE IX.—Epithelioma of upper lip cured by 600 milligram hours.

CASE X.—Two nodular breast recurrences removed by 2,400 milligram hours.

CASE XI.—Ulcer of upper lip removed by 2,440 milligram hours.

Dr. CHASE of Baltimore had seen Dr. Bissel's work, but felt that there existed no proof of cure by radium. He advocated prophylactic use of *x*-rays following operation and the use of the rays in inoperable cases.

Dr. BISSELL concluded by reporting twelve cases of malignant tumors, six of which had already been operated upon, and seven were beyond removal by knife. These patients now living he declared would have died without radium applications.

Cancer of the Bladder.—Dr. J. BENTLEY SQUIER of New York advocated radical surgery for malignant tumors of the bladder. The methods of cauterization included *x*-ray, fulguration, radium, high frequency, and slow baking. The operative measures were palliative, excision, and resection. Abnormal cell was said to be six times as resistant as cancer cell. The dosage of radium was declared incompletely worked out. It was not known within what range and with what dose a cancer cell might be killed. Two inches was mentioned as the limit of expected radium influence upon the cancer cell. The great expense of radium was a serious objection to its use. Most vesical tumors were pappilomata and should have the radium operatively buried within them to inhibit their growth. Radium might be used postoperatively where there was some doubt of complete removal of tumor cells. Heat was called ineffectual because the cancer cells were buried in the perirectal, perivesical spaces, and glands, and therefore inaccessible to the applied heat. It was necessary to remove at times ureteral vesical opening and internal meatus and in the event of muscular invasion of the bladder by the tumor to remove the glands as well. The vesical neck, Squier held, should not be resected. It was declared impossible to diagnose cancer of the bladder through a cystoscope and often impossible after removal of a piece of the tumor. He advocated fulgarization for unquestionably benign growths. Squier further illustrated his technique by lantern slides recommending putting the urachus on the stretch to expose the obliterated hypogastric and subsequently the vas which indicated the vesical end of the ureter. The positions of the ureters, he said, were necessary to be known before the bladder should be retracted for division. The bladder should be incised ventral if necessary and, if indicated, the ureter should be divided after ligation. The growth might then be romoved and the cut distal end of the ureter drawn into remaining bladder. Had performed this operation eighteen times with thirteen recoveries seven of whom were living after eight months to three years. Had had five recurrences.

(To be continued.)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

The Two Hundred and Sixty-eighth Regular Meeting, Held Friday, February 5, 1915.

The PRESIDENT, Dr. WALTER B. JAMES, IN THE CHAIR.

Unusual Cases of Lymphangioma. — Dr. ABBE made these presentations:

CASE I.—A boy, Richard N., aged 4 years, who presented a universal purple birthmark from his right waist line to his toes, with unusual features. At no point was the nevus entirely smooth, but presented a granular surface on a purple base, which did not blanch on pressure. Many of the areas were more rough, while over the knee and popliteal space, down on the calf and along the front, over the instep and around the ankles, were extensive areas of greatly thickened, rough, hypertrophic tissue with adherent crusts and hard epithelioma. In some places it had bled and oozed and so added to the crusts, giving a dark and ominous look. The parents had taken him to a surgeon in New England with no promise of relief and then went to Dr. J. B. Murphy in Chicago, who saw no way of curing the child and referred him to Dr. Abbe. It seemed probable that radium wolud be favorable if the case were a lymphangioma. Dr. G. T. Elliot saw the case and confirmed the diagnosis. Dr. Abbe had twice gone over the entire surface with radium, with marked improvement. The rough surface of some parts had smoothed and as much fading as could be expected had been noted. Some of the thick masses on the calf would now receive more attention, and Dr. Abbe said he would hope to show him cured in a year or more. Such a large lesion had to be aproached with caution. Microscopic study of a piece cut from the calf showed wholly lymphoid growth.

CASE II.—A man, Peter D., 25 years, who was perfectly well as a child, but at 13 years the tongue began to swell, so that for three weeks it was difficult to talk at school. The tongue was never normal after that and continued to swell during the twelve years. Four years before Dr. Abbe saw him he had a rapid increase in swelling, making it difficult to eat or talk. This lasted three weeks and left the tongue larger than before. A third acute accession happened five weeks before Dr. Abbe saw him. It then began to be painful. From the first it had occasionally bled. Examination showed the left half from tip to base, enormously swollen so as to cling to the roof of the mouth. The surface was rough, hard, and covered by thick gelatinous secretion and clotted lymph. It had an irregular, lobulated, purple aspect, unlike any tumor of malignant type. Nowhere was the tongue pink or of usual papillary surface. Under the tongue large tortuous veins and firm swollen mucosa was seen, filling the floor of the mouth on that side. The right half tongue was normal. Speech was thick and difficult and offensive clotted slimy secretion was constantly an annoyance to him. He had been obliged to give up work on account of the pain in the tongue. The massive tongue was about 2 inches thick. Dr. Abbe began radium applications cautiously on March 9, 1910, and in one month there was marked improvement and he could take the photograph shown. Proceeding cautiously he had it half cured in 6 months. At that time the patient was shown to the Practitioners' Society. In one year the surface was quite flattened. Dr. Abbe now gave more attention to the bulk of the tongue and sublingual cavernous angioma and lymphoma. The patient was now cured and had remained well for two years.

CASE III.—This patient, Ethel W., a girl of 7 years, was first seen in April, 1914. Five months previously

a small lumpy sore appeared beneath the tongue, regarded as a canker sore, and was cauterized by silver nitrate. It grew rapidly. Dr. Coolidge sliced it off. It bled and grew rapidly again. It was excised thoroughly under ether when it had become as large as "the end of the finger." It was a curiously granular sort of tumor and went to pieces during removal. It grew again in one week, pushing up under the tip of the tongue. It was now as large as the end of the thumb. It was again carefululy and thoroughly removed. Microscopical examination showed it to be lymphangioma. It again returned rapidly. It was then burned out under ether by cautery. In four weeks it returned. The patient was sent to Dr. Fordyce, who burned it out well. It soon came back larger than for two months and quickly became the size of a marble but spontaneously reduced somewhat as if it were partly cystic. When seen by Dr. Abbe it was a hard, bean shaped, spherical mass, a half inch from the tip of the tongue. It was buried in the tongue and discharged a bloody fluid from an opening on the under side. The whole aspect was that of a hard lymphangioma. Dr. Abbe applied radium for one-half hour, squeezing the growth between two radium cells to compress the growth and cross-fire it by radiations. In ten days the tumor was half its size, and though the tongue was sore for four days the growth then quickly disappeared. For ten months it had remained practically cured.

Case IV.—This patient, Lenore G., girl, 3 years, had since birth a disfiguring mass of pale vesicles on the right side of the neck on the collar line, two inches wide by four inches vertically. The masses were mostly clean, not inflamed, a few were dusky or dark, and it was said some of them darkened and then scaled off. Dr. G. T. Jackson diagnosed them as lymphangioma circumscripta, a rare but classic lesion, which could be cured by ignipuncture of each lymph vesicle, which, of course, would leave a group of scars. He hoped that Dr. Abbe could cure them with radium without scar. Dr. Abbe said he ventured to use the strongest radium, for one hour only. The lesion was cured in six or eight weeks, following a radium erythema. The vesicles which were of the size of rice grains were all cured, but six or eight outlying ones which had not been treated.

Dr. Abbe said he thought Dr. Brewer would agree with him that these cases were hopeless from a surgical point of view. Case I was a mixture of lymphangioma and hemangioma. They responded to radium treatment almost better than any other lesion.

A Case of Recurrent Fever from Rheumatic Infection without Articular Manifestations.—Dr. L. A. Conner presented this case. He said it presented a very unusual temperature curve for what was unquestionably some form of rheumatic infection. It concerned a young man of 18 years, who had had an attack of rheumatic fever four years before, and a second, much milder attack, one year before. Following the first attack, he showed some mild cardiac symptoms and was told that his heart was weak. During the past year he had shown occasionally some palpitation and some dyspnea on exertion. Three weeks before admission to the hospital he had for two or three days mild pains, without swelling, in his ankles and feet, and about two weeks before admission he developed fever which he thought had continued uninterruptedly up to the time of his admission. With this fever there was some malaise, loss of appetite, and some sweating at night, but no other symptoms either local or general. Pain, swelling, and tenderness of the joints were entirely lacking. Upon admission he presented the signs of an old aortic insufficiency, but otherwise the physical examination was negative, except slight general enlargement of superficial lymph nodes. His temperature ran persistently high 102.5° to 104.° for eight days, and then fell by lysis to normal. After remaining normal for twelve days it rose gradually and ran high for eight or ten days and again fell by lysis. After being normal for two weeks it again rose slightly and remained slightly elevated for some ten days, when it returned to normal and remained so permanently. During all this time there were no local symptoms of any sort to explain the fever, except that now and then there was slight pain and very slight tenderness in one of the finger joints and in the left shoulder. No change could be detected in the heart signs at any time during the illness. During the periods of fever his blood showed a well-marked leucocytosis. Three blood cultures were negative, as were also the Wassermann and Widal reactions. No petechiæ were found either in the skin or in the mucous membranes. At the end of the third period of the fever the patient made a good recovery, the signs of his aortic insufficiency remaining unchanged. The view that the recurring attacks of fever were of a rheumatic origin, in spite of the almost complete absence of joint symptoms, seems to be confirmed by the fact that in each of the three periods of fever the temperature began to subside almost immediately after the patient was put upon intravenous injections of sodium salicylates, although little or no response to the use of salicylates by mouth could be noticed. If the assumption that the fever was the expression of a rheumatic infection were correct, it was interesting to speculate upon the question as to whether the fever was due to an acute exacerbation of an old rheumatic endocarditis, or whether the circulation of the rheumatic poison, without evidence of localization, was in itself sufficient to give rise to recurring attacks of prolonged fever and high temperature.

An Unjustifiably Correct Diagnosis. — Dr. Huddleston presented this case. In February, 1912, he saw a widow, 46 years old, with a tumor of the left breast which was later removed by Dr. Blake, and was shown microscopically to be cancer. In April, 1914, Dr. Huddleston saw her again. She had suffered eight months with "stomach trouble," which had been severe for the last four months. She had lost weight and complained of lack of appetite, nausea, heartburn, and attacks of diarrhea. She had had no stomach pain. Some years before she had had a similar attack, lasting several months and ending in complete recovery. The physical examination showed nothing abnormal in in lungs, heart, or abdomen. The urine showed a very faint trace of albumin, but was microscopically negative. The systolic blood pressure was 145. The uterus was retroverted, but competent gynecological examination stated that the pelvic condition did not account for the symptoms. Regulation of the diet, bowels, and stomach was tried without effect. She was compelled by weakness and vomiting to go to bed. There was evidently a nervous element about the case. She was discovered by the nurse apparently endeavoring to induce vomiting and her apparent condition changed sometimes with miraculous rapidity from wretchedness to comfort with the introduction of some outside element. The test meal examination showed total acidity 39, free hydrochloric acid slight trace, no lactic acid, and no blood. Another test meal taken somewhat later showed the same result. In June the patient again got up, began to eat freely and kept down extra meals without trouble. At this date an Abderhalden test was made by Dr. Lowy of Newark, N. J., for cancer, and the result was positive. In July there were several discharges of blood from the bowels, attributed to piles. The fecal discharges at other times appeared normal. Nausea and vomiting returned, the patient was confined to bed, but would stay in comfort for 24 hours or more if not urged to eat. In August the condition improved and the patient gained six pounds. In September an *x*-ray examination, which had been advised in the spring, was made in New York. The patient was brought in an ambulance from her home and was in such a low condition that the wisdom of moving her was questioned. The *x*-ray showed that the stomach and duodenum were deformed by some more or less circular mass, and it was considered probable that there was a tumor at the head of the pancreas, and in view of the previous history this tumor was probably malignant. The diagnosis was then made of cancer of the head of the pancreas. In November the patient gained weight, again got up, and began to eat. In December she developed tonsillitis and pneumonia and died at the end of the pneumonia, as the result of an acute kidney condition. At the autopsy gallstones were found and an adhesion holding up the splenic flexure so as to form a constriction at that part of the bowel. The descending colon and sigmoid flexure were only about the thickness of the finger. The organs were submitted to Dr. Ewing, who reported that the stomach was much reduced in size and deformed by peritoneal constrictions, especially about the pylorus, that microscopically there was diffuse chronic interstitial productive gastritis with atrophy of the glands, that in the peritoneum over the pyloric region there was found a minute focus of fibrocarcinoma loosely attached to the greater curvature. Near the pylorus was a pea-sized lymph node of fibrocarcinoma. The pancreas was firm; its head was abnormally prominent, causing a slight irregularity in the course of the duodenum. The parenchyma showed slight fibrosis but no traces of carcinoma. A lymph node, the size of a pea, on the supe-

rior pancreatic artery was the seat of old tuberculosis and also alveolar carcinoma, the two lesions overlapping in the same tissue. The colon was the seat of a pronounced chronic mucous colitis and there was a productive and exudative inflammation throughout the mucosa. The kidneys showed moderate parenchymatous degeneration. It was obvious that the cancer, although existent, was not significant in causing the symptoms or death. The symptoms were due to interstitial gastritis with possibly related gallstone irritation and to colitis.

Dr. EWING said it seemed possible that these nodules of fibrocarcinoma might have regressed completely had the patient lived. Some had apparently done so already, as he found no tumor cells in some of the scars. The association of tuberculosis with fibrocarcinoma in the same lymph node was rare and interesting. This small tuberculous node seemed to be the only tuberculous focus in the body. The chronic gastritis was very advanced and in the colon there was a very extensive chronic croupous inflammation with large masses of firm adherent fibrin and almost complete atrophy of the mucosa over wide areas. A luetic origin was not probable, but there was a history of severe acute gastroenteritis, "ptomaine poisoning" which might have led to the chronic inflammation. The result of the Abderhalden test was interesting as showing how such tests might lead one astray, for Dr. Ewing believed with Dr. Huddleston, that the traces of carcinoma did not cause the symptoms or the death. He was not prepared to express a decided opinion on the Abderhalden test. Two workers in their laboratory had long been occupied with the technique of this test, but they had not secured enough controls to determine how often the reaction occurred apart from carcinoma. In this case the test was positive, cancer was present, but was not the cause of the prominent symptoms.

Observations on Twilight Sleep.—Dr. JOHN W. BRANNAN presented this paper. (See page —.)

Dr. WILLIAM M. POLK said that the subject was an extremely interesting one. We owed it to our patients to investigate the matter thoroughly. They had the right to claim any help the medical profession could give them. The arguments for contraindications in this case were strikingly like those which appeared at the introduction of chloroform. Dr. Metcalf first used chloroform in midwifery in this country. He received much criticism at the hands of the profession and commendation at the hands of his women patients. He developed a large obstetrical practice on this ground. The attitude of the women was identical with that described by Dr. Brannan. The effects were not unlike those found with the use of chloroform. Chloroform was dangerous in cases of inertia of the uterus not dependent upon nerve irritation. Sometimes with nervous and sensitive women this was found, but leaving out this consideration, with the ordinary cases of inertia and tardy labor you might get hemorrhages. In regard to the child, in chloroform and ether anesthesia the effects on the child were quickly gotten rid of, but the minute you introduced morphine in addition you incurred danger. The combination was dangerous. The advantage to the mother in the parturient state was apparent. As regards exercises Dr. Polk did not see why women should not take them. The handling of women had hitherto been always to keep them very quiet. The point made by Dr. Knipe was questioned by some doctors. He explained the reduction of the uterus to the level of the pubis by the use of exercises. There were other factors in the matter. The size of the uterus was supposed to be that of the "mailed fist" at the end of the second week, but in the minor types of sepsis, not combined with temperature, the involution of the organ was checked. The general muscular condition also entered into the question of involution. If this could be improved he would consider it a very decided change in the handling of the cases. He would share Dr. Brannan's caution suggested in investigation of the influence of the drug upon child life before coming to an absolute decision on the question. In regard to the time of watching, if six hours were necessary that was practically the same thing as with chloroform, especially with primiparæ. The patient apparently suffered less with scopolamine than with ether. With ether she was continuously asleep. Scopolamine was an advantage from the point of view of the mother; it was of no particular advantage from the standpoint of the doctor, and quite as doubtful from the standpoint of the child, especially if morphine be used with chloroform or ether. This summed the matter from Dr. Polk's point of view.

Dr. BREWER said he did not gather from Dr. Brannan's report whether the patients were absolutely unconscious of pain during the uterine contractions. Was there evidence of suffering? Did they merely suffer and forget it afterwards? He had used scopolamine morphine in surgical work. Some years ago he undertook to perform operations with that alone and no other anesthetic. In one case he used it for a major operation. In minor operations the patients gave indication of much pain, although they forgot it. He did not think actual pain was diminished unless a dangerous dose of the drug were used.

Dr. DANA said it seemed to him that more emphasis had been laid on the dangers of this treatment than was warranted by Dr. Brannan's statistics. He was inclined to that view from a report of the Public Health, Hospital, and Budget Committee of the Academy of Medicine, which was based on the opinions of the best obstetricians in the city. He thought Dr. Brewer's point well made. He had wondered why so much stress was laid on relief of pain from the point of view of amnesia. If a man had had a severe toothache and he forgot about it a month after, had he suffered any the less?

Dr. JAMES said that Dr. Brannan's paper was interesting to him because it gave the results of practical observation in a large number of cases. It had more weight with him than the report cited by Dr. Dana, which although based on opinions of well-known obstetricians was largely theoretical. Dr. James had talked with Dr. Cragin, who had not seen many cases, and was not much impressed with it. Dr. James was impressed with the small number of difficulties encountered in a large number of cases. As regards the exercises Dr. Knipe's ideas were very interesting along the line of physiology. He did not think that any physician took into consideration the fundamental elements of intramuscular venous propulsion in the treatment of sick people. The normal individual was active most of the time in some part of the body, and this diffuse propulsion was important to the circulation. Thus, according to Henderson, the filling of the right auricle was important to the work of the aorta. Since time immemorial one had been told that in pneumonia and typhoid an even temperature and quiet were essential, but very actively delirious cases did not suffer the expected ill effects. He believed that people who lived active lives did not suffer so much in proportion. Why then could not a sick man have intramuscular venous propulsion as well as a healthy man? Therapeutics in regard to temperature had been revised—why not revise views of absolute quiet?

Dr. ROPER asked Dr. Brannan if the patient had to have chloroform when the child's head passed over the perineum?

Dr. BRANNAN said yes; that might, in the language of the imaginative German, constitute an "isle of memory." In reply to Dr. Brewer he said that in one case there was analgesia without amnesia. Another woman who kept crying out did not remember anything afterward. Dr. Knipe stated that if memory were destroyed, shock was absent; such shock as would have occurred after labor. That was in line with Crile's ideas on anesthesia. In reply to Dr. Dana he said he thought the report of the Academy was based on the opinions of older men who considered the methods of ten years ago. At that time there was nothing like the careful, methodical way of applying the treatment that Gauss had devised. Dr. Knipe had got good results because he had applied the ideas in the best possible way. As to operative interference Dr. Polk would tell them what the percentage of forceps cases was. In their cases it was 5 or 6 per cent.

Dr. POLK said that under choloroform anesthesia it was nearly as large.

Dr. BRANNAN said in regard to the exercises and muscular atrophy he had seen patients after ten days' illness very much weakened and unable to stand. These women had been through a severe physiological illness and in three or four days were up and about. He did not remember that in cases he used to see. The interest of the women was particularly striking.

Keratosis Follicularis Spinulosa.—J. L. Bunch reports the case of a boy aged 4 years in whom the first skin lesions had been noticed eighteen months before on the neck and later on the arms, back and abdomen. They consisted of small acunimate papules, pale in color which were even more perceptible to the touch than to the eye. To the hand they gave the sensation of a nutmeg-grater but they gave no subjective symptoms.—*Proceedings of the Royal Society of Medicine.*

SOME COMMON VOICE TROUBLES IN SINGERS*

By IRVING WILSON VOORHEES, M.S., M.D.,

NEW YORK.

Voice, which may be looked upon as a resultant of the highest efficiency which our combined special sense organs are capable of, is one of the most important of all our body functions. Sudden loss of voice is a calamity akin to the loss of sight or hearing, and yet we seldom pay any great amount of attention to this fact unless it is thrust upon us by some experience which lies close to our individual happiness and well being.

In this inquiry I have thought it worth while to consider those voice troubles which are of physiological significance, leaving out of account organic difficulties such as chronic disease, tumors, polyps, cord paralysis, etc.

A broad outlook upon the entire voice problem leads us to some very interesting and important generalizations. One needs to remember that in singing, not merely the larynx or lungs or resonators are used, but the muscles of the chest wall, the diaphragm, the abdominal group, the spinal column, the ears, and most of all perhaps, the brain. Voice is a highly specialized body function and calls upon every member of our organism when in most active use. In singing and to a less extent in speaking the whole body must be used to secure artistic and persuasive effects.

In obtaining and maintaining these effects certain social considerations and general habits of life are of great importance. Excessive smoking, eating or drinking, unbridled sexual license, inhalation of dust and dirt, bad food, chronic constipation and diseases of the gastrointestinal tract in general, road travel, and irregular hours of working and sleeping—all these have a marked influence upon the voice. Very frequently the singer has prolonged rehearsals from which he hurries home, eats a hasty meal, rushes back to the theater or opera house and goes through with his part in the performance. Neither his voice nor his stomach has sufficient time for rest. Furthermore, the demands made upon the singer's mental capacity are often enormous. Ten or twelve different parts may have to be learned during a season. This is particularly true of "understudies," who must always be ready to fill the place of an indisposed artist at a moment's notice. Consequently more rehearsing and more mental and physical work are performed than the highly organized nervous system is capable of. It is no wonder that by the end of the season many singers suffer from nervous breakdown or find their voices deficient in quality, strength and endurance.

The stage and the auditorium communicate directly with each other and are separated at times only by a curtain; therefore very considerable differences in temperature are present, and after the curtain goes up the lightly clad singers are exposed to a severe draft. Moreover, when stage scenery is shifted about a large quantity of dust is set free in the air. An enormous amount of dust is scattered about also in those productions in which there is much dancing. The temperature of the house is unbearably high and the ventilation is very bad. Loss of moisture from the atmosphere causes dryness of the mucous membrane of the entire respiratory tract.

Managers and directors who are responsible for such conditions and who have it in their power to correct them should be publicly censored for such disregard of the commonest principles of sanitation. When they begin to understand that box office receipts are often directly influenced by what goes on "behind the scenes" some steps may be taken to ameliorate these exceedingly objectionable conditions. In some public halls dry sweeping is the rule. It is easy to imagine therefore the condition of the atmosphere when the curtain rises. Obviously the proper time to clean up is after the night performance. At this time the house should be thrown open to the winds of heaven and the vacuum cleaner should be put to work. Ventilation of theatres and opera houses is disgraceful in this day of preventive medicine and public enlightenment upon health questions. In many places the only fresh air that gets in during the winter struggles through during the hurried opening and closing of doors. The air is so vitiated that one finds it almost impossible to keep awake. At intermissions the exits are kept as securely shut as the portals of a 16th century cloister. Prevention of death by slow asphyxiation should be looked after as carefully as prevention of death by fire.

Acute infectious diseases are responsible for many of the singer's ills. Nearly all of them are air-borne infections whose portal of entry is the upper respiratory tract. The first symptoms are referable to mucous membrane disturbances and are often classified under that all-embracing phrase "a cold." Enanthems would in all probability always be found if we were capable of recognizing them. Accurate knowledge of infantile paralysis began only when Flexner and his assistants first studied the nasal secretion in children affected with this dread disease. Scarlet fever, diphtheria, measles, and influenza all begin with symptoms in the mucous membranes.

So-called "catarrh" of the upper air passages is one of the most frequent causes which brings

*Candidate's Thesis presented and accepted for admission to the American Laryngological, Rhinological and Otological Society, February, 1915.

the singer to the physician. In general it involves the entire respiratory tract, nose, nasopharynx and oropharynx, larynx, and trachea. Only a few types of this disease do not follow this order. It is very important in all singers to make a thorough examination of the nose, nasopharynx, larynx, and ears.

Hajek's investigations have shown that while in normal nasal secretion very few pathogenic micro-organisms are present, in the secretion from chronic rhinitis one finds Friedlander's Pneumo Bacillus, staphylococcus pyogenes, and the streptococcus pyogenes. We see therefore that infection of the larynx may occur from above and that it is unwise to pencil with silver nitrate, to use electricity, inhalations, etc., without relieving the causal condition which lies higher up in the respiratory tract. Some authors have gone so far as to say that a more or less pronounced chronic catarrh of the upper air passages is present in almost all singers. Ideal structure and function of the respiratory tract are found only in the rarest cases.

Anterior rhinoscopy frequently shows a puffy condition of the inferior turbinates in singers. This may be pillowlike, elastic and very red, but uniform in color. In other cases there is maceration, and loss of the superficial layer of the epithelium which is thrown off and forms crusts on the surface. In such cases there is considerable sticky secretion also present. In a third group one sees a pale and irregular turbinate showing fibrous areas or humps (hyperplastic rhinitis) with a small amount of secretion. Sometimes this is the beginning of an atrophic condition, and is associated with a feeling of dryness. If one examines a cross section of such a hypertrophied turbinate, one finds increased vascularity and widening of the cavernous spaces. The ciliated epithelium is still intact but below this there is a small zone of round cell infiltration. The gland acini and the connective tissue are not changed. If the cavernous spaces are filled with blood, the turbinate is very markedly enlarged and can entirely occlude the nose.

When the inflammation has existed a long time the ciliated epithelium is partly lost and is replaced by pavement epithelium. The inflammatory zone has then become larger, the gland acini are infiltrated and as a result of this pathological condition the cavernous spaces are widened and deepened. Finally connective tissue substitution takes place, which brings about pressure upon the glands and vessels, limiting the amount of secretion and leading to dryness of the nose and throat. One should never sing during an acute attack of any infectious disease. To vocalize during an infection of the larynx or tonsils or during an attack of rhinitis or bronchitis may permanently damage the vocal mechanism.

Nasal or head resonance is such an important factor in all good singing that the rhinologist should make a special effort to diagnose accurately all causes of diminished or imperfect head tones. If one asks a singer to hum and then presses each nostril alternately the slighest difference in resonance between the two sides can be easily noticed. If there is soft hypertrophy of the inferior turbinates this obstruction will vary from time to time, so that not too much stress should be placed on a single examination. Soft hypertrophy acts like a cushion wherever it be situated and is of relatively greater importance in singers than bony obstruction unless this latter be especially marked.

It is a great mistake to operate upon a singer's nose without first trying what can be done by conservative measures. This matter is I believe of special significance with respect to the septum. An anterior septal obstruction, dislocated columnar cartilage, etc., interferes greatly with "pointing" the head tones forward. Careful removal of such obstructions offers in some cases a great chance of remedying a troublesome defect, but if total resection of the septum is practised resonance may be much impaired, particularly if a perforation happens to occur. Even with a perfect anatomical result a "flapper" may prove exceedingly annoying to the vocal artist. It must be remembered that free discharge or dry discharge in the form of crusts may obstruct almost as much bone. Only in case of urgent necessity should a turbinate be removed. The middle turbinates are especially important in singers although they may seem to be of no great value in other persons. Dr. Frank E. Miller holds the opinion that any imbalance from such removal is always followed by trouble in the larynx, especially by a tendency to thickenings and formations of nodes.

The pharynx is of importance since it is the antechamber to the nasal fossæ and accessory resonators. Its size, shape and condition influence tone to a great degree. The effects of adenoids, bands and adhesions, ulcerations, choanal polyps, etc., scarcely need mention. Discharge flowing down from above if not dislodged and expectorated, passes into the stomach or clings to the arytenoids and other parts of the larynx interfering with the production of a clear tone. Pharyngitis granulosa is of no great importance, representing as it does merely an increase in lymphoid tissue. Cauterization of these isolated areas on the posterior wall is usually quite unnecessary.

Pharyngitis lateralis on the other hand is quite important since a swollen condition of the stylopharyngeus muscle strongly predisposes to fatigue of the larynx. The lateral walls of the larynx should on this account be carefully inspected at each examination by means of the post-nasal mirror or pharyngoscope.

The posterior wall of the pharynx is for the most part at rest and does not produce many symptoms, but if the lateral walls are diseased, the palatal arches and neighboring parts, there can be much interference in tone production and also in the enduring power of the voice. Fatigue, which is a threatening symptom in many singers, may be caused by this condition as well as by faulty placement. Incorrect methods of singing and forced effects, bring about the same result.

There is a form of pharyngitis which is rather suggestive of an associated digestive disturbance. Imhofer has called this "pharyngitis dyspeptica." Pathologically there is dilation of the veins with cork-screw-like appearance and varicose changes in the esophagus. There is also a pickle-like appearance of the mucous membrane either in the buccal cavity, in the pharynx, or in indefinite spots such as the pillars of the throat which appear sometimes pale, sometimes livid in color. Not every gastrointestinal disturbance, to be sure, shows this condition in the pharynx, but it does

occur. It is not usually associated with nasal disturbances but may extend into the larynx if untreated.

The influence of the faucial tonsils on the singing voice has been a matter of much controversy. Some months ago a book on this subject was published in which the author collected the opinions of some of the best singers, speakers and laryngologists. The result is that we are just about as much in the dark as we ever were; for positive statements both for and against tonsillectomy are set down about equally strong. There seems to be no reasonable doubt that diseased tonsils do affect the singing voice just as other diseases in the respiratory tract affect it. It should be understood that the size of a tonsil has little relation to its pathological significance. Very large tonsils if healthy may cause no symptoms whatever save the disadvantages due to size; while a tonsil so small that it can scarcely be seen may cause no end of trouble. In January, 1915, I had under treatment a soprano of large florid, healthy type who suffered so much from severe pains in the right posterior pillar, base of tongue and right side of larynx that she was at times unable to fulfil her engagements. Seven different physicians made seven different diagnoses ranging all the way from "catarrh" to spinal cord tumor. I likewise failed at first to locate the cause, but upon drawing back the anterior pillar with a blunt hook and making pressure against the superior pole of the tonsil, several beads of foul whitish material were forced out. The tonsil in this case seemed no larger than a split pea but contained three badly diseased crypts, local treatment of which was followed by complete disappearance of the pain which had not returned during the two months following.

The risks of removing tonsils in singers are, of course, much greater than in other persons, and it is well to study the patient a half dozen times and see what can be accomplished by local applications. Each crypt should be reamed out with a finely wound cotton application, thoroughly irrigated and then reamed out again with a finely wound applicator moistened with 40% silver nitrate solution. This should not be done oftener than every other day, longer intervals sufficing according to trial. If two or more attacks of tonsilitis have occurred within one year, and if after careful local treatment cheesy masses can still be dislodged, operation should be considered. Several good authorities, notably Miller, do not remove the capsule. Personally I have not proved to myself as yet that any good reason exists for conserving the capsule, but I am open to conviction. Whatever the method, great care should be taken that no injury is done to the pillars, for a contracting scar may pull the uvula and palatopharyngeus muscles out of alignment and appreciably affect the singer's vocal power and resonance.

All of the four tonsils, the uvula, arch of the tongue and false cords must be considered when studying the problem of interference. The lingual tonsil is of special importance in that it may become so enlarged as to press upon the epiglottis. When infected it can give rise to a series of symptoms not the least of which is a troublesome cough. Enlargement of the lingual tonsil is seen in almost all cases of pharyngitis dyspeptica due to hyperacidity of the stomach. If the secretion flows down the pharyngeal walls into the larynx there may be redness of the vocal cords, slight paresis of the approximator muscles and hoarseness.

Leaving out of account the acute infections which give rise to laryngitis such as inhalation of noxious fumes, smoke, etc., the causes of laryngeal disturbances in singers are muscle insufficiency, fatigue, hysteric aphonia, cough, and hypersecretion.

When the vocal cords are highly inflamed they are shorter, thicker and less mobile than when normal. Hence the laryngeal muscles have to work much harder than usual in making the infinite variety of fine adjustments of which the larynx is capable. Muscle fatigue and phonasthenia must be the result. There is sufficient reason therefore for not allowing vocalization during congestion of the larynx whatever the cause of such congestion may be. One must examine carefully the anterior commissure of the larynx in all cases. This region which can only be seen when the patient sings a high note is commonly a site for "catarrh" in singers. Thickening of the cords in the angle of the commissure and infiltration may extend to the entire cord substance and musculature leading to greatly impaired function.

Muscle fatigue may be due to insufficient removal of waste products of which phosphoric acid is perhaps the chief. There may be also deficient oxygenation from either a poor supply of good blood, or a good supply of poor blood, as in cases of anemia, chlorosis, etc.

Finally muscle insufficiency may be due to defects of innervation, the defect being of central origin, disease of the brain or bulbar paralysis, or of peripheral origin due to paresis or paralysis of a recurrent laryngeal nerve from whatever cause.

In singers' fatigue (phonasthenia) there is often a stretched feeling in the sides of the throat especially when high tones have been used a great deal. There is a feeling of insecurity especially noticeable in middle voice when singing pianissimo. In order to keep the voice from breaking, the throat is gripped by the strong muscles and "set." The singer stands with head thrown back, abdomen forward, face strained, grimaced and very red. There is a tendency to slide off pitch into a lower note. Muscular contractions instead of being tonic become clonic and the expired air instead of flowing out in a steady stream escapes in jets giving rise to a tremolo or irregular variations in intensity and heigth. In this "squeezing" act the muscles used in pressing together the vocal cords are the cricoarytenoidei lateralis and the interarytenoidei. All movements of the true cords are accompanied by the action of antagonistic muscle groups, free play of which is necessary for modulation of varying tonal heights. Fatigue symptoms are most frequently seen in "sung out" voices, muscular atrophy from age or disease, tremor senilis and simple nervousness.

Hysteric aphonia is not unlike blepharospasm in the eye. There is complete loss of mental control over the vocal mechanism. If a singer goes on the stage indisposed and illy prepared, sudden fatigue may come on as a result of extreme nervousness and a form of aphonia may ensue. This phenomenon which is called *Lampenfieber* by the Germans is fortunately merely temporary as a rule. However, when called to a case of this kind one must not be too hasty with a diagnosis before making a careful examination. The actual cause of the aphonia may be a bleeding into the cords. Schnitz-

ler and Hajek report such a case in their book, published some years ago.* During the performance of a great opera the prima donna was noted to be in good voice during the first and second acts. In the third act, however, after a sudden sharp outcry she became absolutely aphonic. Examination on the following day showed the left vocal cord relaxed and suffused with blood. In a few days resorption began and in about four weeks the voice became normal. A few months later the same accident again occurred. Rest, astringents, and proper measures to prevent a recurrence finally produced a cure.

Laryngeal cough is frequently of nervous origin. It may also become a mannerism and it then detracts markedly from the singer's influence upon his audience. Funke has ascribed reflex cough to the faucial tonsils. It seems, however, to be more frequent when the lingual tonsil is diseased. Some authorities ascribe it to false breathing. Pressure of the clothing such as a tight collar should not be overlooked.

The question of vocal nodules (chorditis nodosa) will be discussed in the paragraphs dealing with technique.

Tracheitis is very common in singers. It is not different in general from catarrh of the air passages elsewhere. There are redness and swelling of the mucous membrane so that the outline of the cartilaginous rings disappears. Later a thick, lumpy secretion is cast off, which is removed by violent and repeated coughing. Such a condition is frequently very stubborn and disturbs the singer very much in his work.

What now are the results of the catarrhal diseases of the upper air passages upon the voice? The nose and nasopharynx, as we have seen, are of great value for resonance. The so-called head register finds almost its entire resonance in the accessory cavities. Moreover, the chest tones set the air in these cavities into vibration. It follows that if these hollow passages are narrowed or closed by any pathological process whatever, the voice shows diminished resonance, lacks timbre, and is, one may say, "dead."

Just a word as to hearing. While the ears need not be perfect for the reproduction of a melody, any imbalance in tone appreciation may cause the artist to sing off pitch. Most of such cases are due to disturbance of the sound-conducting apparatus. Impacted wax or a Eustachian catarrh with rarefaction in the middle ear are the most common causes of this defect. It is an interesting fact that both Beethoven and Robert Franz were stone deaf, but this was not of congenital origin, of course. Alt mentions two patients who were principals at the Vienna Hofoper. One of these had no idea of the strength of his tones and hence sang sometimes too loud, sometimes too soft. The other did not know that he heard about a half tone deeper in his right than in his left ear.

Imhofer mentions an opera director who ran away abruptly from a dress rehearsal because he found trouble with the pitch in one ear. A large ceruminous plug was removed, with perfect restoration of tonal interpretation.

Various disturbances of the musical sense, such as amusia, musical alexia, musical agraphia, etc., have been described. They are of central origin and are very uncommon.

One need scarcely more than mention the general diseases which affect the voice. Most of these are harmful in that they cause ulcerations in the larynx, loss of substance of the vocal cords, scar tissue, and synechiæ. Diphtheria and syphilis are typical of this pathological dyscrasia. Certain diseases produce affections of the laryngeal joints leading to restricted motion of the cords, which may be mistaken for paralysis. Rheumatism is occasionally found in the cricoarytenoid joint. Its prognosis is ordinarily favorable. Our lamented friend and colleague, Dr. William Kelly Simpson, reported a unique case of gonorrheal fixation of this joint.

In typhoid there may be suppuration of the laryngeal cartilages or joints followed by paralysis during the convalescent stage. Pharyngitis and laryngitis are, of course, very common with typhoid.

Every laryngologist sees cases of laryngeal tuberculosis. Some authorities, notably Imhofer, advise deep breathing in tuberculosis and look upon singing as a valuable adjunct if the case be not too advanced. *A priori* this would not seem to be advisable. I have had no experience in this matter.

Anemia and chlorosis have already been mentioned. When they are associated with obstipation and intestinal atony the voice is poor in quality, indistinct, and of particularly disagreeable timbre.

There are spongy turbinates and much secretion in diabetes. Dropping in the throat, hoarseness, and cough are common symptoms. Freudenthal has described diabetic ulcerations in the respiratory passages. There is also a condition which occasionally occurs in diabetes known as "laryngoxerosis," the voice troubles of which are described by Leichtenstern as xerophonia. This complex consists of dry throat, marked tendency to voice fatigue, and a lacquered appearance of the vocal cords as if they were covered with gold leaf. Such cases must be rare.

The relationship of sex to nose and throat conditions in singers is a matter of some importance. Many cases of tonsillitis in newly married persons have been reported. It is supposed that sudden stimulation of the sexual function brings about a tonsillar reflex, but this is not well understood. Imhofer reports the case of a woman patient who began to menstruate between periods as a result of cauterizing an inferior turbinate. It is important that female singers should not vocalize during menstruation. At this time the blood pressure is increased, there is congestion of the upper respiratory tract, the sensorium is out of harmony with externals, and hence resonance, timbre, volume, and carrying power are affected.

Voice culture should be prohibited during pregnancy. After the third month the entire body undergoes marked changes. The abdomen begins to interfere with normal respiration, the muscles of the chest and throat become easily fatigued, there is diminished power, and loss of both quality and effective expression.

During the climacteric there are many bodily disturbances which may affect the voice, such as dryness, paresthesias, and tickling sensations. The voice may, however, remain fresh and unchanged.

We come now to the matter of voice technique, a subject which is fraught with difficulties, but one which is of fundamental importance.

In a recent volume dealing with the tonsils and

*Since writing this essay I have had a very similar case, the lesion occurring in the left vocal cord as pictured in Hajek's contribution. The patient, a well-known vaudeville singer, suffered sudden severe hoarseness and pain while singing during an attack of laryngitis. Recovery took place in about six weeks.

the voice problem the author says, "It is beyond the knowledge and absolutely out of the sphere of physicians to judge of maladies of the timbre of the voice, of affections of the middle register, of the solidity, intensity, compass, agility, etc., etc." I submit this statement to every thinking laryngologist for analysis and reflection. Not only should the voice physician know at least in a general way the technique of correct singing, but he should be so trained that he can make a diagnosis of the singer's difficulty by his ear alone. This is by no means so hard as it seems. Anyone with a correct ear who has the fundamental facts at hand and who listens to many varieties of singers for a few weeks will find himself able to assist the artist materially in this regard. Many singers are sent to the specialist who are not in need of his services, but whose chief and imperative requirement is the skilled advice and leadership of an experienced voice teacher.

The average specialist knows nothing of voice training and the average voice trainer knows equally little of the anatomy, physiology, and pathology of the nose and throat. The great confusion which now exists in vocal training, and the lack of standardization of vocal methods, are the direct outcome of this age—long disparity between vocal art and vocal science. Laryngologists should cooperate with the vocal teacher in every possible way, teaching him those facts which are derivable only from a sound medical training, and learning from him those elements which are indispensable to artistic voice work.

The laryngoscope which was invented by a great singing teacher, Manual Garcia, is seldom or never found in the hands of the singing teacher of to-day. On the other hand, many specialists do not know how to "try out" a voice at the piano, and cannot tell after hearing an aria whether the singer kept to the pitch or whether his resonance, breathing, and technique in general were anywhere near correct. This is a kind of knowledge which is not difficult to acquire, and those of us who do not acquire it deserve to be censured for our ignorance.

The matter of diagnosis is of prime importance to everyone concerned. Every beginner in vocal culture should be studied both by the vocal teacher and laryngologist, a careful record of all findings should be kept by the latter, and a copy of the same, together with such advice as seems necessary, should be sent to the teacher. Every case is individual and must be considered in a broad and thorough way. It will sometimes puzzle both teacher and laryngologist to determine how and why certain undesirable elements are present in a voice, but there is a much better chance of this being discovered as a result of "team work" than if considered by either alone.

Breathing is the first and most important act in singing. There is a marked difference in the breathing of a beginner and an advanced student. The frequently recommended "forced breathing" is not to be advised for beginners because they do not possess the skill of controlling the volume of air.

Beginners should breathe through the nose with the greatest possible ease, but not too deeply, using little more breath than in speaking. One of the greatest mistakes in breathing is made in the production of high tones: In taking a high note the vocal cords are set in close proximity or rather are set firmly against each other and only a small quantity of air can pass through. It is folly, therefore, to fill the chest with air and attempt to force the entire lung capacity through this narrow chink. Straining drives the blood toward the head, producing redness of the face, and perhaps injuring the voice permanently. The pupil must learn to breathe automatically and use only sufficient air to produce tone, the residual air being held in reserve for large effects or to sustain a prolonged tone. As a result the vocal apparatus will not be injured through straining and will simply be subject to such diseases as may befall it accidentally. Many individuals make a mistake in throwing the tone out in order to bring it forward, instead of placing it properly, and then allowing it to flow forth into the resonance spaces. Through jerking a tone, the entire voice can be shattered. Tremolo and uncertainty soon result and a clearness becomes impossible. The fundamental condition of good tone production is softness, and only by this means can one bring the most pleasing and fullest effect to the air. Every hard effect diminishes the beauty of the voice, which loses its splendor through continued ill-treatment. Not that one should always sing pianissimo, but the stream of air should pass out almost of itself and leave behind a feeling as if the mouth and nasopharynx were filled with tone. When one sings fortissimo there should be a feeling of complete tone control, and during the greatest swelling of tone full elasticity of the muscles participating must be present.

There are in reality two chief kinds of production, the open and the closed. The open corresponds to the so-called chest tones, the closed to the head tones. Middle voice is simply a variation between thoracic and head production; that is, between the open and closed types.

Emphasis should be placed on head production, because here it is that the various cavities of the head function as tone distributors. The sinuses of the head are like the sounding board in the violin; the value of the instrument depends chiefly upon its resonating qualities.

Every correctly placed tone must take origin in the larynx, sail gently upward as far as the soft palate, and there divide, part going into the nasal cavities, part against the hard palate and teeth as directed by the movements of the tongue.

Tone which is produced by the larynx alone is thin and lacks timbre and sustaining power. Only by the aid of the accessory resonators is it transformed into musical sound having color, timbre, and carrying power.

Good tone is not produced in the larynx, chest, mouth, or nose, but is made vibrant and resonant by the entire body. One can feel it with the fingers along the entire spinal column, and can get it from a thoroughly resonant wooden floor if the stethoscope be applied to the floor while the singer sustains a big, full vibrant note.

A tone series is made by linking each tone to the next succeeding tone through an overtone. The junction of greater intervals must produce variations in color if these tone connections are produced upon one and the same vocal sound.

In functional testing of a voice one must have the patient go up and down the scale pianissimo in varying key. Then ask him to sing a song or aria and judge of the strength, enunciation, sense of rhythm, tone character, quality, and errors of placement. Frequently one will be surprised to find a "hole in the voice" where it is impossible to sustain a tone. All notes above and below this point may be correctly, even beautifully, sung, but the hole is

always in evidence. The physician may be unable to find any pathological cause for such an occurrence. Correction of this defect belongs for the most part to the vocal teacher.

One of the great faults is singing out of one's compass. The pupil whose voice is naturally a mezzo-soprano is trained for coloratura work, or a baritone, who might attain some success if confined to his own range, is taught tenor roles to his ultimate dissatisfaction and perhaps ruin.

Some authors deny the existence of a specially constructed vocal apparatus. They do not believe that a soprano has one type of organ, the tenor another, and the bass still another, but there are undoubtedly marked differences. The tenor's vocal cords are only about one-half as broad as those of the bass, and the cords are in general shorter. It is at times almost impossible to say whether a given singer should be instructed as a tenor or a baritone, since there are many types which shade into each other. It sometimes happens that we find a singer who is a baritone during one season and a rather poor tenor the following season. This screwing up (*hinaufschrauben*), as the Germans call it, is a common cause for voice fatigue and early voice decay. The primal result is hyperemia of the overstrained organ which leads finally to dilatation of the vessels of the vocal cords and predisposes to catarrhal secretion.

Fatigue of the vocal muscles is noticed by the singer much earlier than by the physician. If neglected, relaxation of the vocal cords and loss of clear definition of tone occur. If we follow the singer who has changed from baritone to tenor we find that his productive period is quite short, and after repeated breakdowns, the efficiency of his voice becomes less and less, and its splendor finally goes. There seems, however, to be a very general anxiety to climb the heights attained by the tenor. A like condition holds for mezzo-soprano and soprano. In artistic circles there exists the opinion that alto voices are rare and do not last long. The fact is that composers have written less music for contralto and alto voices than for sopranos, and the female singer must, therefore, study parts which do not lie within her range; for example, Ortrud and Brangane.

Young boys and girls frequently appear on the stage much too early. They have not yet acquired a satisfactory technique, and consequently they do not go far before suffering artistic shipwreck. Those who are by nature and art not fitted for a stage career should be informed by the conscientious specialist and voice teacher in order that they may take up some other profession before it is too late.

Just a word about singers' nodes. These small excrescences may be looked upon as corns upon the vocal bands. They are about the size of a small pinhead, are found usually at the junction of the anterior third of the cords with the posterior two thirds and always situated on the free vibrating margin. As a point in differential diagnosis between nodes and other tumorlike bodies, Imhofer lays stress on the color and smoothness of surface of vocal nodules which are exactly that of the cords themselves.

The pathology of vocal nodules has been studied rather carefully by several investigators, notably by Chiari and by Hajek. Chiari found in 16 cases enlarged mucous glands, hyperplasia of the epithelium and fibrous tissue with many round cells interspersed. Fortunately the epithelial and glandular elements may both retrograde through rest and change of voice method. The condition is found most often in tenors and coloraturas, although it is seen in mezzo-sopranos, baritones and bassos. The singer often complains that the voice cracks or has a film over it. He tires easily and is very insecure, especially in soft voice work. When straining for a high effect the cords turn slightly on their long axis and the nodes may roll out of the way.

All possible sources of cordal irritation must be removed, strict rest must be enjoined for at least four months, and special exercises must be given in soft voice before the singer can gradually be allowed to go back to work. The principal thing is to prevent a recurrence. Surgical removal is nearly useless unless the production is absolutely changed. Astringents, such as salicylic and lactic acids, alum, and weak adrenalin, may be used. The long oval type of node is highly glandular in structure and retrogrades faster than the more fibrous variety.

Great hindrance is found by many singers in so-called "interference." Interference is found at the false vocal cords, at the base of the tongue and at the soft palate. When the larynx musculature is incorrectly used, especially in striving for "big tone", the muscles are set so that the two false cords come close together and hinder free flow of the column of air on its way upward.

Interference at the base of the tongue is a very common fault not only in beginners but in advanced singers who have not been properly trained. The base of the tongue rides upward, crowding against the epiglottis and soft palate, giving the so-called "throaty effect." This is well marked if the lingual and faucial tonsils are hypertrophied.

Soft palate interference is frequently due to nervousness, particularly to self-consciousness. It can be prevented by teaching the pupil how to breathe through the nose with the mouth open, a feat by no means simple as everyone knows who has tried to make a posterior rhinoscopy with the mirror.

In closing, let me say a few words about vocal prophylaxis, hygiene, and therapy. The singing voice is very easily impaired and loss of the same without demonstrable cause occasionally occurs. If the physician has been unfortunate enough to treat such a case just previous to the aphonia he may be summarily haled to court. On this account every method of treatment, especially every operative attack upon singers must be weighed in the balance many times and the intended procedure with possible complications should be fully explained.

Singers are, perhaps, more open to suggestion than any other class of patients. They are sometimes hypochondriacal and constantly worry about their condition. For this reason it is sometimes well that a singer does not know too much about the anatomy of the vocal apparatus, for he will ever after ask "Have I vocal nodules?" or "Is there any paralysis of my throat?" and it will be exceedingly difficult to convince him to the contrary.

Prophylaxis should be the watchword with every singer. Before beginning voice cultivation a careful diagnosis should be made by a rhinolaryngologist who is skilled in vocal analysis, and the entire mechanism should be put in as good condition as possible. Care of the mouth is of great importance. The absence of a front tooth, an ill-

fitting set of false teeth, Rigg's disease, a short frenum, etc., all affect the enunciation. Oral hygiene should be practised after each meal.

As for the nose, prevention of acute rhinitis is the first essential. Exposure to draughts, irritating fumes, and dust are harmful. The feet must always be kept free from dampness. Linen mesh should be worn next the skin. It is preferable to silk, woolen or cotton. If salt solution be used in the nose it should be physiological salt solution (0.6 per cent.). Imhofer reports a case of anosmia from the repeated use of strong salt solution.

The collar should be low and large, the neck free. A cold douche for the neck and chest upon arising protects against the chills of a changeable climate. Massage is of course beneficial both as body massage and localized (vibration). The physical strength should be increased by exercises. Gymnastics may be practised in a small room by means of a mechanical exerciser. Breathing exercises are of great value as are rowing and swimming. Bicycling and automobiling may be harmful from inhalation of dust and violent air currents.

Vacation should mean a complete rest in a quiet place with plenty of good, wholesome food seasoned only mildly.

Total abstinence from alcohol is not absolutely necessary, but very mild wine or good beer should be used only in small quantities. Alcoholic laryngitis may occur in those who refuse to obey this mandate. There is no great harm in a mild cigar after a good meal, but cigarettes ought not to be used as the paper in which they are rolled burns with an irritating vapor.

The steamed-out air of our houses and theaters makes the mucous membrane very dry.

Every singer should learn to save his voice as much as possible. Yelling, loud talking, rasping, and scraping are injurious. Upon the slightest tendency to hoarseness the whisper alone should be used. There is no necessity for using one's full capacity at rehearsals. If any difficulty with the voice is noticed, the teacher and laryngologist should be consulted at once in order that the correct diagnosis may be made and the proper remedy applied.

One should avoid drugs that work too energetically in the larynx of singers. The vocal apparatus in singers is a very fine and fragile mechanism, which requires careful and delicate treatment. To attack it with caustic agencies is comparable to oiling a watch with wagon grease. One should employ operative methods as a last resort. Every square millimeter of mucous membrane in the upper air ways is important and should not be removed unless absolutely necessary. The resultant scar, while unimportant to the average person, may be of great significance to the singer. Réthi reported five cases of neuroses which developed after operations in the nose with adherent scars. Even the smallest obstacle, the slightest uncomfortable sensation may work unfavorably upon the high-strung sensorium of the singer. The upper air passages should be cared for, in which case the larynx may do very well without special treatment. A 5 per cent. solution of protargol for the nose is very useful and is widely recommended. Rosenberg recommends a mixture of boric acid and tannic acid powder equal parts for application to the larynx. This sometimes relieves a laryngeal catarrh after two or three applications, but as a rule the use of powder in singers' throats is unadvisable. Tannin may sometimes be used in 10 per cent. glycerin solution. In the atrophic forms of chronic nasopharyngeal catarrh, massage with or without medication has undeniably good results. It causes a certain turgescence of the mucous membrane and increases secretion. In the hypertrophic forms of catarrh it is useless.

After an application of protargol to the larynx the singer should not use the voice for at least two hours. Protargol is especially indicated in hypertrophy of the turbinates where there is superficial crusting. It brings about diminution of secretion and crusts, and regeneration of the epithelium. There is of course some reaction after protargol, but it is less than after silver nitrate.

Inhalations have been used for a long time in the treatment of voice troubles. Imhofer thinks they are worthless, giving as his reason that when warm steam enters the larynx it increases hyperemia, which we especially do not wish. Inhalation does help remove secretion, but there are other means equally effectual. Inhalation sometimes gives a sense of weakness and fatigue in the larynx. At certain "cure resorts" it seems to be beneficial, but probably the climate, regular modes of life, and discipline are the real causes of this improvement.

Every case must be studied individually, and while no class of patients is more grateful than singers, no other class requires such absolute attention to every detail of life and art. Considering the long years of training the relatively short working period, the constant nervous strain, and the irregular routine life of the singer, he deserves our warmest sympathy and praise.

11 Central Park West.

HUMAN CONSERVATION.

By Mau'de Glasgow, M.D.,

New York.

When we wish to convey a clear and definite idea of the value of an article it is a very common practice to speak of it in terms of dollars and cents. The dollar sign is a wonderful clarifying agent. Material wealth has hitherto taken precedence of every other kind, its interests have been carefully guarded and laws for its protection have been numerous and efficient. On the other hand, there is overwhelming proof that human life in the mass has had but little relative value, and where the two interests have clashed that of humanity went down to overwhelming defeat. But our own age has seen the dawn of a new day, and now the beams of its rising sun are brightening the whole civilized world. We have discovered that human life *has* a definite material value—that the premature demise of a normal individual is a distinct civic and national loss, and the effect of this knowledge has been a change in our mental attitude so great as to be almost revolutionary. Knowledge came, and wisdom with hesitancy and diffidence initiated effort to conserve human life as well as that of cattle, fishes, and other forms of organic and inorganic life which had hitherto monopolized the country's efforts in the conservation field and depleted exchequers. The will to count the cost is a long step in the evolution of human solidarity, and a spur to the interest in public health movements discernible everywhere.

The science of human conservation is necessarily comprehensive as well as of univeral interest. It

comprises, besides the control of contagious and the supervision of other diseases, all other questions bearing on the general human welfare. It includes therefore problems of clean and wholesome food and drink, of housing, of overcrowding, of sunlight and fresh air, of alcoholism, and the control of social disease, of eugenics, segregation and care of the feeble-minded and abnormal, of child nurture, child labor, industrial conditions generally, and many others. The public health movement seeks to remove those obstacles which stand in the way of human progress, to prolong life, and make that life of greater usefulness and value.

Professor Irving Fisher, a member of the Roosevelt Conservation Commission, found that the United States suffered the loss of 600,000 preventable deaths annually, which, excluding the diseases of childhood during the first seven years, were caused by typhoid fever, tuberculosis, accidents in industry, and pneumonia. The same author assumes that at least one-half of those lying on sick beds are suffering unnecessarily, and that the loss every year from these avoidable illnesses and from premature death amounts to a very large sum. One authority believes that the country sustains a loss from typhoid fever alone of $100,000,000 annually. Literature disseminated by the North Carolina State Board of Health in 1912, showed that 40,000 out of 160,000 deaths were preventable, and involved a loss to the State for that year of $45,000,000. The reports of the Minnesota State Board of Health show that Minnesota suffers a financial loss from two diseases—typhoid fever and tuberculosis—of nearly $15,000,000 annually.

The experiences of these States are doubtless being repeated with some variations all over the country, and while the material loss looms large, there is a sadder, a more pitiable waste of sighs and tears, a toll of human misery that could and should have been avoided.

We have about 35,000 fatal industrial accidents every year, many of which occur among the strong and vigorous. Then there are others, perhaps more to be deplored, where a hand is suddenly and painfully amputated, an arm twisted and wrenched off, a leg mangled, torn, and crushed to a pulp, and the young, hitherto strong and self-reliant individual is made a cripple for life. New York has in the short space of three months seen as many as 1,900 of these largely preventable accidents, while there are of course a large number which have never been reported at all.

In many States the laws relating to industrial accidents are inadequate and easily evaded, and when the unforeseen catastrophe occurs, besides the immediate victim, there are frequently dependent relatives who are deprived of all support and cast helpless upon the community.

While the employer and the State are responsible for the conditions under which the employee must labor, so that the health of the citizen is not injured, his earning capacity impaired or his life destroyed in wealth producing industry, it is equally binding upon the employee to utilize all the aids to prevention of disease or of accident which have been provided for him, and not through sloth or indolence to disregard or neglect the health-preserving and life-saving measures furnished for his use.

It is, however, unhappily true that many an industrial and other worker is obliged to acquiesce in the conditions thrust upon him, though in accepting them he is aware that he is risking health, strength, long life, and happiness.

Industrial diseases are varied and under present conditions their effect upon the human organism is often pernicious, impairing the vitality of the worker and shortening his expectation of life. Work in general we know to be a good thing, an essential to health, and it is a pity through unintelligence, indifference, or greed, so to pervert it from its legitimate use, that it becomes an instrument of disease and death rather than an aid to health and long life.

We have occupational exposures to extremes of heat and cold, to damp atmospheres, to air laden with dust and irritating fumes predisposing to pulmonary and kidney affections. Some suffer from varicose veins, flat-foot, and knock-knee from constant standing. Mineral poisoning due to contact with the metal is very common. Lead poisoning meets us everywhere, causing, besides colic, palsy and anemia, affections of heart, kidneys, and circulatory apparatus. Plumbism has been caused by handling silk fringe weighted by means of lead. Dressmakers have been poisoned by biting off the ends of dyed thread. Arsenical poisoning with consequent multiple neuritis and paralysis has resulted from sleeping in a room the walls of which were covered with green paper.

Not only are workers in furs exposed to poisoning by arsenic through their occupations, but the wearers of garments impregnated with this substance may also suffer from poisoning—eleven samples of furs out of forty-two having been found dangerous to the wearer.

Industrial disease frequently approaches insidiously, fastening its grip upon the victim, sapping energy and vitality, until at an early age he is overpowered, losing his efficiency or dying at an early age, leaving behind him a family unprovided for, to starve on the wages of their unskilled labor, and to increase that great army of untrained workers who are just able to exist on what they earn and whose vitality and efficiency are necessarily always at a low ebb.

Occupations which compel women to stand upon their feet all day, while a fruitful cause of suffering to the individual, have a no less pernicious effect upon the offspring. In the absolute disregard of physiology, where the woman breadwinner is concerned, and in defiance of the fact that every young woman is a potential or actual mother, we find the source of much of the lowered vitality and susceptibility to disease of the whole nation. Woman has been deprived of the right to secure for herself the most favorable conditions under which to labor, and this much needed protection she has not received from any source. Carrying a double burden—that of breadwinner and of motherhood—she frequently stands on her feet ten hours a day or longer, while pelvic diseases are indueed by the unnatural strain upon sensitive, highly developed organs. Physical strength is drained away, a susceptibility to abortion is developed, puny infants are born to die of marasmus, or tended by the social welfare worker to linger on to a wretched, weary maturity. The report of the Children's Bureau of the Federal Government with regard to infant mortality, shows the effect upon expectant mothers of laborious work and poor nutrition, in the high death rate of their infants.

In factories where women work, and some are obliged to remain constantly upon their feet, it

should be possible to have a change of occupation—to rotate from one kind of work to another, the worker becoming expert in two kinds of work, so that there would be no financial loss, or adjustable seats might be arranged so that the requisite rest would be obtainable.

The length of the working day is receiving serious consideration, and it is a very interesting fact that under the eight-hour system the cost of production is reduced. American weavers receiving $1.60 per day can successfully compete with Japanese workers who are accustomed to receive eighteen and a half cents per day for the same kind of work. Overfatigue, physical strain, nerve tension prolonged for twelve hours or so dull the senses, destroying the mental alertness, and the keen perceptions demanded by the best quality of work. Another question bearing on human welfare is the minimum wage. It has been found that raising the wages increases the efficiency of the worker, but apart from that fact, women, as mothers of the race, should receive protection and wages sufficient to support them in health. Insufficient and poor food lowers vitality and causes susceptibility to disease, besides conducing to immorality. When a girl needs a pair of shoes or a new shirt-waist it ought not be necessary for her to go without breakfast for some time in order to procure those articles. A strong and vigorous nation was never mothered by overworked or debilitated women. It is equally evident that even a strong and healthy child needs protection from strenuous work during the early years of his mental and physical development. Child labor is an industrial evil which scars the child and marks with a sinister brand the community which permits it, resulting inevitably in a decrease in racial strength and vigor.

"Only the human father,
A man with power to think,
Will take from little children
The price of food and drink.

Only the human mother—
Degraded, helpless thing!—
Will make her little children work
And live on what they bring!

No fledgling feeds the father bird!
No chicken feeds the hen!
No kitten mouses for the cat—
This glory is for men.

We are the wisest, strongest race—
Loud may our praise be sung!
The only animal alive
That lives upon its young."

We discovered long ago that individual health was dependent upon communal health, so Boards of Health were formed and these have grown and developed until in large cities the Health Board is a center of specialized endeavor, generating and controlling currents of activity which beneficently affect the public welfare. New York city can point with pride to its low death rate, 13.40 per thousand for 1914, which in spite of climatic drawbacks places it in the front rank of healthful cities. A century or two ago the annual death rate was, in civilized countries, forty or fifty per thousand, and even higher. The mean expectation of life in London in the seventeenth century was about nineteen years, while at the present time it has more than doubled that figure. In the United States our gain seems to be largely in self-limited diseases and the maladies of childhood and youth. Some other affections show increase rather than diminution. Diseases of the heart, circulatory apparatus, and kidneys, diseases of the nervous system, cancer, and diabetes are said on good authority to have increased about 131 per cent. in the past thirty-five years. And this abnormal death rate is found among the foreign-born population as well as the native American. It exists in suburban as well as in urban localities and is found in every State in the Union. We have some millions of citizens over forty years of age, who have thus reached the time of life when these insidious, chronic, and often fatal diseases manifest themselves, and these individuals are, by reason of acquired skill or wisdom, of great value to the State, so that the death of these persons at an early age, is from the financial point of view alone, most deplorable. The fact that this increase in the diseases of maturity is not paralleled in some of the older European countries where the mode of life is simpler and less strenuous provides food for serious thought; and it is both interesting and encouraging to know that Sweden, successful pioneer in public health activities, has improved the chances of life at all ages. This Scandinavian State has firm control of all social diseases, used here in the broad sense of the term, such an intimate and complete knowledge of cause and effect, such a comprehensive grasp of the whole question, and such skill in dealing with each phase of the problem, that the vitality of the Swede has been so enhanced that his expectation of life is the longest and his mortality rate the lowest in the world. The next few years will doubtless see a great deal of time and thought devoted to the science of keeping people well and increasing their vitality. Panacea, the restorer of health, must give place to her sister Hygiea, the conserver of good health, and though we may not reach the 140-year limit, which Metchnikoff thinks is the normal span of life, we know positively that the normal human being living in harmony with nature's laws can live a long and useful life. It is unfortunately true that either because of our ignorance or neglect of the basic laws of life, we see the vigor and boisterous energy of the Old World emigrant disappear in a generation or two. It is a pity, for the chance to win in the battle of life is poor unless there is a good constitution to lean on. The possession of sound health, of staying quality, often determines the question of success or failure. It is the healthy individual who is the most efficient, the most valuable, and the cheapest worker. Every individual has an inalienable right to be born well, nor has society a right to manufacture invalids or criminals. We must resist the forces which convert the "singing man" into a State's prisoner and place him in a dark, damp, disease-breeding cell, which steals his health and embitters him against the world. And if we win to life the marantic infant, straighten the bowlegged and prop up those who must still totter instead of bounding along the highway of life, we must be careful not to do this at the expense of valuable citizens spending *them* in the service of others less valuable than themselves.

A very close study of all abnormal beings should be made. Men and women possessing the mentality of children should be placed in institutions and protected from exploitation. These grown-up children with fully developed bodies and darkened minds should not be allowed to exercise their awful power for evil.

Human conservation must take cognizance of all

the weak points in society's armor, and either mend them or end them. Mothers should be taught that the undernourished child is prone to disease—that the seeds of incurable maladies are often planted in childhood, and that there is a difference of about 5 inches in the well-nourished and the poorly nurtured child.

Practically every class in the community needs instruction or reminder with regard to the question of individual health. The influence of bad example is very striking. Many who are theoretical guides of others ignore, where they themselves are concerned, the most simple rules of hygiene. Errors of food and drink are common and digestion waits not on appetite but rather on convenience. The relation of fatigue to efficiency is a closed book to many, and the absolute necessity for periods of rest and recreation does not receive sufficient attention. It is no uncommon sight to see those who have already reached the crest of life's hill and are ready to descend the other side eat and drink without physiological demand as they did in their vigorous youth, and at the same time live and work at high pressure without a thought of the inevitable result.

College athletes, spurred on by the vociferous admiration of their fellows, and in spite of their own knowledge and the care of their examiners, subject themselves to such severe physical strain that the hypertrophied cardiac muscle in later life, when the activity is more mental than physical, shows signs of degeneration and weakness which are absent in the classmate whose college life was less strenuous.

And yet the art of play is of the highest importance—but not its abuse. As a nation we probably do not play enough or relax sufficiently often. Our neglect in this respect has no doubt an important bearing on the neuroses, psychoses, and the nervous instability so prevalent in the present age. We drive through life at such a pace that we have no time for repairs until the machine goes to pieces. It is a costly procedure, expensive all the way through, for the tired person is necessarily inefficient for the time being and quite inferior to himself when rested. Probably nowhere in the world do the people live at such high pressure as in the United States. In the older countries one is born to a certain station in life and has no ambitions beyond it, but in this country the newsboy on the street is a potential president of the most progressive nation and the richest country in the world.

Part of our morbidity and mortality comes from disease to which the patient has voluntarily exposed himself and it is idle to overlook this fecund source of crippled minds and bodies. Arthur Hunter of the New York Life Insurance Company shows from the examination of 2,000,000 insured lives that persons suffering from syphilis have an extra mortality of 80 per cent., although the patients in question had all received treatment—some of them two years' treatment without intermission. Syphilis, we know, predisposes to tuberculosis. The immoderate use of alcohol lies at the root of many degenerations and predisposes to many evils. Then, too, the diseased, the decrepit, and the mentally feeble are permitted to propagate so there is always a crop of incapables coming to harvest.

The era of preventive medicine upon which we have entered is no doubt the beginning of a successful scientific effort to reach the source of that secret drain upon our resources which is daily depriving us of many valuable lives and which would be a staggering load for a smaller or weaker nation to carry. Not until all the sources of national weakness are eliminated can we expect to be a sane, sound, rational, and happy people. The problem must be viewed in its entirety and all classes and conditions placed under conditions favorable to their best welfare. As public opinion governs the world a sentiment must be created which shall demand a maximum of good health and of physical development, strength, and efficiency. If necessary, force may be employed for this purpose, just as education, which is perhaps less necessary, is compulsory. We have with great effort and at much expense created a machinery to educate the child; we shall now learn that it is still more necessary to build up and develop his body. We shall know better in the future than to cram with unrelated fact the half-starved anemic youngster in the impossible task to make him learn while his stomach is empty. We might as well expect to run a motor car without gasoline as to educate under such circumstances.

And we must not begin with the child, we must start with his parents, insure a good heredity and then protect and cherish what has been received. The body must be nourished before the mind is fed, even if we have to pass a mother's pension for that purpose. If we now spend billions of dollars in war pensions, though beneficiaries have been sometimes deserters and frauds, we can afford to feed where necessary the future citizen. And as the "common people" are the backbone of the nation's life, and their resources the most limited, they require special attention. But, indeed, even the most favored classes need protection—from themselves, and instruction and assistance in the search for health and longevity.

Popular talks and public lectures on health and hygiene help to enlighten the social conscience on this subject, as well as magazine articles on the same topic. It will certainly be helpful for the layman to know that it is not only the lean, narrow-chested individual who is susceptible to the germ of tuberculosis, but also the apparently hale and hearty human whose environment has been of the most favorable kind, but who unhappily in some, at present obscure manner, is especially vulnerable to the tubercle bacillus; and that tuberculosis often begins in childhood and that it dwells in the sumptuous apartment as well as the dirty underground cellar. No less valuable should be the knowledge that diabetes has trebled itself during the past three decades, that this malady is one which follows in the wake of an habitual generous diet; that the disease is unusual where the diet is scanty and plain.

In view of the insidious onset of many diseases which secure a hold upon the victim long before he is aware of their presence a thorough physical examination every year or so seems a necessity, so that the disease may be discovered and eradicated while there is yet time. Insurance companies and other large bodies have already discovered the value of this plan and are thus pioneers in this phase of public health work.

The periodical examination of supposedly normal persons, many of whom measure well up to the average, will, apart from their value to the examinee, furnish valuable statistics which may affect the opinions gathered from a mass of clinical findings obtained from diseased subjects, and which have been handed on from one generation to another and accepted without question. This opinion

is sustained by the examinations of some hundreds of average women of different classes, but all breadwinners, made by the writer.

Some medical authorities have contended that the physiological reverberations of women were normally attended by discomfort or pain, perhaps both; but statistics gathered as indicated show there is no basis for such a conclusion, that on the contrary, the majority of healthy women living normally and not subjected to undue physical strain experience no pain whatever. One young woman declared that her physical strength, buoyancy, and energy seemed increased rather than lessened during the periodical crisis. The clinical picture changes, however, when the subject is forced to do work which taxes her resources too heavily, such as standing on her feet all day. Any kind of physical or mental fatigue will sooner or later manifest itself in the majority of cases unpleasantly. The writer found in 180 cases selected at random and including professional women, factory workers, and other women in the working class that 100 suffered no pain whatsoever, 70 experienced some pain, and 10 very severe pain. The ages ranged from 17 to 47, and the majority were unmarried women. Of the 70 who suffered slight pain, 9 occasionally suffered no pain at all. One of those examined had never suffered until after she had borne the burden of caring for a sick friend when she was for a prolonged period deprived of rest and sleep while carrying heavy responsibilities. One never suffered pain unless after working unusually hard. Another had never suffered until twelve months ago, but was now having trouble periodically.

In the professional class 59 per cent. did not suffer pain at all; 42.6 of the factory class did not suffer, and 56 per cent. of the domestic class women did not even experience discomfort. In the first class 37.6 per cent., in the second class 46.1 per cent., and in the third class 38.6 per cent. experienced slight pain, while of those suffering severe pain there was in the first class 2.5 per cent., in the second class 11.5, and in the third class 5.3 per cent. The figures just given would indicate that freedom from dysmenorrhea is in the majority of instances dependent very largely upon a favorable environment. Gallons of ink and reams of paper have been used in writing of the physiological disabilities of women, yet the conditions which produce these drawbacks remain practically unaltered. It is probable that periodical examinations will result in placing the menopause at a later period than formerly and influence the accepted view as to its semipathological character. It is interesting to observe in these examinations the influence of the past and present environment on different individuals. In some are noticed normal stature, fairly well developed bodies, and evidences of attention to all the functions of the body. Other groups show shorter stature, indicating in many cases, no doubt, defective nutrition in childhood, or perhaps overwork or mental strain at an age too early to be safely borne. In the latter class obstinate constipation is frequent, in some instances but two or three evacuations a week, and an accompanying indigestion. Teeth are often defective and not so well cared for as they might be. Many of the girls in this class are slim and fragile in appearance, as though possessed of little reserve strength and so susceptible to adverse influences.

The domestic class women were for the most part sturdy and well developed. Not a few of them were of Slavic origin. Most of these had worked in the fields in their youth and many showed a development of the right side, including shoulder and arm, very much superior to the left. The diet to which they had been accustomed in their native land consisted in part of rye bread, potatoes, fresh country products, and good milk. Meat was rarely used. The teeth of these women were, as a rule, excellent and the physique robust. In this group constipation was not usual as in the former class, and the general health was decidedly better.

Blood pressures were found to vary considerably. A few middle-aged women in apparently robust health and without subjective or objective symptoms showed blood pressures between 200 and 225 mm. Some showed a temporary increase in pressure, probably due to excitement.

Periodical examinations will afford an opportunity to note the effect upon heart, lungs, and general condition of different groups of workers detailed to different phases of the same kind of work, thus making it possible to alter plans if signs of overstrain make their appearance.

So long as the object of periodical medical examinations is to benefit the examinee and to put her in a better physical condition, it seems important to have the required medical or surgical attention as early as possible while the psychic effect is still present. The patient will then be more amenable to advice and more likely to carry out instructions. It does not seem advisable to ignore the natural feelings of reserve and modesty which most women possess. These rather deserve encouragement, so that when women, and especially girls, require treatment peculiar to themselves and prefer one of their own sex to afford them such treatment this preference should receive respectful attention just as it would if they belonged to a different sex. These preferences have a natural basis and their brushing aside is often attended with distress of mind to the interested party for which there is no moral justification.

Printed instructions as to the character of foods and their properties, how to care for a weak digestion, and how to avoid constipation would be valuable to many. Hints with regard to the effect of fresh air, exercise, and the importance of securing the requisite amount of rest and sleep after working all day would be of benefit to many young people unable to plan wisely for themselves.

The work of Human Conservation represents a vast sea of social activity composed like the tributaries which unite to make the majestic river, of many channels of effort, all working in unison toward the same great end—to add to the happiness, usefulness, value, and longevity of the human race.

110 East Eighty-first Street.

MODERN PHASES AND TREATMENT OF BASEDOW'S DISEASE.*

By O. HENSEL, Ph.G., M.D.,

NEW YORK.

ADJUNCT VISITING PHYSICIAN, GERMAN HOSPITAL, NEW YORK; INSTRUCTOR IN CLINICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

We all know of the important rôle which ductless glands play in certain diseases of the body and are gradually becoming aware of the fact that it is rather rare to find either clinically or on the post-mortem table disease of the one without some evi-

*Read before the Clinical Society of the German Hospital, New York, Jan. 8, 1915.

dence of lesion in one or more of the others. It is thus quite proper to speak of them all as one system. This is not the place to go into the complicated and as yet imperfectly understood function of this endocrine or ductless system or its individual members; suffice it to say that their duties are manifold in that they exercise an effect upon the growth and metabolism of the body, on the correlation of the visceral nerve functions and probably also on the disintoxication of the system. These glands, among each other, may act either in a compensatory fashion or antagonistically or both. An interesting chapter of these studies is the relationship of the thymus to the thyroid in Basedow's disease and its influence upon treatment.

Basedow's disease is no longer the simple clinical entity described by Karl v. Basedow about 75 years ago. Numerous other symptoms were discovered besides the three cardinal ones; the varying course, from a benign condition hardly to be separated from neurasthenia, and often mistaken for this, to a truly explosive and malignant type was carefully studied. In certain mild types, the symptoms may come on only during menstruation, to disappear during the interval when the diagnosis may be impossible, while in the most severe cases, death may set in in a few days. Finally, the treatment has undergone considerable modification. From a truly medical condition, the disease was soon placed on the border line, and to-day, is almost universally claimed by the surgeons as their own.

For practical purposes, we may include among Basedow's disease (1) Hyper- or dysthyroidism or the formes frustes; (2) Basedow's disease proper, and (3) Basedow's disease with pronounced thymic symptoms. By hyperthyroidism we really mean dysthyroidism inasmuch as Klose[1] has conclusively shown that the expressed juice of the Basedow thyroid, injected intravenously in small amounts into dogs will cause pronounced symptoms with a change in the blood picture, suggesting Basedow's disease and similar to an acute iodide poisoning, while the juice of a normal thyroid, injected in the same way even in much larger amounts, will usually give rise to no symptoms. This difference can be detected only if the juice is absolutely fresh, and this probably accounts for the failures reported previously by so many other experimenters. The test is said to be so delicate that it can be used in doubtful cases to determine the Basedow character of an excised gland.

Clinically, in dysthyroidism usually two of the cardinal symptoms are absent or poorly developed, the only cardinal symptom present being the enlarged and vascular thyroid. But even this may not be very evident if the enlargement is chiefly downwards. The characteristic feature, however, is that usually one or more of the minor symptoms are present and often are so pronounced that they form the main complaint. It is therefore not difficult to see that the correct diagnosis is often not made and the real condition is overlooked. Many of us will recall cases of persistent diarrhea that have been treated for a long time as colitis or other conditions, when a more careful examination would have disclosed the ear-marks of dysthyroidism. In many of the cases the symptoms present are wrongly attributed to neurasthenia or psychasthenia, though it is quite true that in these affections sympathetic irritation may show itself in the form of tremor, tachycardia, rise of temperature, and even slight exophthalmos without however an enlargement of the thyroid. In fact, it is quite possible that neurasthenia proper may have an intimate relationship to the ductless glands and many authors have reported good results from the hormone therapy. A fact not generally known is that the chief sympton which bothers some patients with dysthyroidism is a rise of temperature. In these days, when so many patients fuss with the thermometer of their own accord, you may have a patient present herself to you who for months had 100° to 102° every evening without apparent cause except a slight fullness of the neck, a very moderate tachycardia, and a moderate degree of general nervousness and tremor. Cases of this kind may be suspected of subacute endocarditis or of tuberculosis, though the physical signs and tests are negative. The question of temperature in dysthyroidism and Basedow's disease has been interestingly discussed by German authors who believe that it is almost always due to tuberculosis. That, however, tuberculosis is not so common in dysthyroidism and there are cases where the evening rise of temperature can be explained only by the thyroid affection, due to disturbances in the heat-regulating mechanism, is without doubt. In other cases, the loss of weight is the chief symptom, and here again tuberculosis may be suspected, or diabetes, if there is also alimentary glycosuria. That the diagnosis of all these conditions is at times difficult is clear, and we instinctively turn to the laboratory for confirmatory evidence.

The laboratory evidences of thyroid intoxication as postulated by Kocher are chiefly the presence of a mononucleosis in the blood with a delay in the coagulation time. Less commonly, there is also a leucopenia with a relative increase in the eosinophile cells. It has always seemed to me that Kocher has laid too much stress upon the diagnostic value of a mononucleosis. Through the kindness of Dr. I. Adler, I have recently had the opportunity to investigate the records of between 500 and 600 blood counts made on patients such as ordinarily consult a physician in his office. This list includes chiefly cases of disturbances of metabolism, chronic diseases of the viscera, neurasthenia, and chronic infections, such as syphilis and tuberculosis. All diseases of the blood and the thymolymphatic system were excluded. About 2.5 per cent. suffered from dysthyroidism or Basedow. A mononucleosis of over 35 per cent. was present in 27 per cent. of all the cases; over 40 per cent. in 5.5 per cent. Huhle[2] similarly speaks in a recent publication on the "Diagnistische Ueberwertung der Lymphocytose." Among 110 cases of a similar material he found lymphocytosis in excess of 30 per cent. in 45 and recommends that only figures over 40 per cent. should be regarded as true lymphocytosis. Conversely, in series of 20 cases of dysthyroidism or Basedow that I have had occasion to examine hematologically during the last year I have found an absence of relative lymphocytosis, that is under 35 per cent., in three. Often, the apparently more severe cases will show a less marked lymphocytosis than the more benign ones so that the differential count can by no means be employed to gauge the severity of the disease. Thus, in three sisters whom I had occasion to observe, the one least ill showed the highest percentage of lymphocytes. In one case, where I made four differential counts within eight days, figures varying from 28 to 37 per cent. were obtained, showing that extraneous factors also undoubtedly have an influence. I may add here that according to modern

research the lymphocytosis of Basedow disease is caused not by the thyroid but by the thymus intoxication and that a return of the blood picture to normal occurs only after thymectomy, an argument that is not generally accepted but is used by many authors to prove that the thymus is really the organ at fault. In one case of thymectomy published, the mononuclears rapidly dropped from 40 to 10 per cent. Halsted[3], however, has seen a return to the normal several years after thyroidectomy. Borchardt[4], finally ,found an increase of the mononuclears in almost all the diseases of the ductless system of glands.

The determination of the coagulation time of the blood seems to be a more valuable test which also allows of a differentiation from the opposite condition, hypothyroidism. The great disadvantage here is that we have no really reliable and inexpensive instrument at our disposal. I have obtained the most satisfactory results with capillary tubes in a thermos bottle which are broken off at regular intervals. All my cases showed a delayed coagulation. There are, however, plenty of other conditions where a delayed coagulation occurs.

A test, full of promise but not yet generally employed in America owing to difficulties in technique, is the Abderhalden serum test. In the serum of all cases of exophthalmic goiter examined by Lampe and Fuchs[5] ferments were found which digested Basedow thyroid, thumus, and ovarian tissue and sometimes even the tissue of normal thyroid. The intensity of the reaction and the number of organs digested stood in no relation to the type or severity of the disease. These experiments prove that the extreme views as to thyroid or thymus involvement do not hold, but that in probably every case we have a polyglandular syndrome.

In turning now to Basedow's disease proper, the chief interest to-day relates to the participation of the thymus in the pathogenesis of this disorder. Markham as early as 1858 demonstrated a case of cardiac disease with enlarged thyroid and thymus and exophthalmos, and 20 years later, Moebius found an enlarged thymus at the autopsy of a case of Basedow. Very many similar cases have been reported since then and there are even authors who hold the extreme view that Basedow's disease is always thymic in origin. Though by no means generally accepted, the following, almost unbelievable case, of v. Haberer[6] seems to bear out the statement that the removal of thymic tissue so small as to be unrecognizable with the naked eye may bring about a cure: The patient had undergone a thyroidectomy and even a ligation of the vessels of the remaining lobe. When he presented himself at Innsbruck, he was cyanosed and almost pulseless. There were present exophthalmos, a positive Graefe and Moebius tremor, and dyspnea. The right lobe of the thyroid was slightly enlarged, the left not palpable. The heart and liver were hypertrophied, there was slight icterus, a shadow under the manubrium sterni, no dullness, and no compression of the trachea. A small amount of apparently fatty tissue was removed and v. Haberer, very much disappointed, gave up the case as hopeless. To his great surprise, an almost immediate recovery set in so that the patient could be discharged two weeks later virtually cured of all his symptoms. He presented himself again at the clinic three months later a different person and again able to do a fair amount of work.

The effect of the thymus upon the thyroid has been carefully studied experimentally and seems to be both reciprocal and antagonistic. The reciprocal effect is proven by the following:

1. After thymectomy, the blood picture returns to normal as after thyroidectomy, but more rapidly.

2. Injection of the expressed juice of the thymus as well as of the thyroid intraperitoneally will give rise to Kocher's blood picture.

3. In one case, six months after thymectomy, regressive changes were found in the thyroid.

4. Implantation of normal thymus into thyroidectomized dogs will prevent the appearance of cachexia strumipriva.

5. According to Biedl[7], the only one who succeeded in bringing about a complete symptom complex of Basedow in animals was Bircher, who implanted not the thyroid but the hyperplastic thymus.

6. Embryologically, both glands are closely related, there often is a distinct parallelism in size, and the injection of both thyroid and thymus extract will cause an increase of the adrenalin in the blood.

7. Basch finally has shown that the pupils react to drugs in very much the same way in the dog, no matter whether the thyroid or the thymus has been extirpated. In both instances there is also an increased irritability on the part of the peripheral nervous system toward the electric current.

In discussing now the supposed antagonistic effect of both glands, we must turn to the interesting researches of Eppinger and Hess[8] on vagotony and sympathicotony. Most viscera are innervated by two systems, the sympathetic proper and the autonomic or vagus systems which are more or less antagonistic toward each other. In many pathological states, a series of symptoms will point to an increased tone in either one or other system. Various drugs can also be used in studies of this kind; thus pilocarpine, physostigmine, and muscarine act as vagotonics, and atropine as vagodepressant, while adrenalin is the chief sympathicotonic drug. We have not yet been able to isolate the physiological vagotonic principle analogous to adrenalin whose duty it would be to counteract the latter and thus keep the innervation of the principle viscera nicely balanced to meet all needs. Nevertheless, it has received a name, autonomin, and is supposed to be secreted by the pancreas. It is probable, however, that all ductless glands elaborate both vagotonic and sympathicotonic substances which are not, however, exactly alike in their action and probably do not influence each organ in the same way. Vagotonism is seen especially in neurasthenia, in the neuroses, and in congenital conditions. Whether a ductless gland dyscrasia is always at the bottom of these conditions it is at present difficult to say. In Eppinger and Hess's cases there was frequently evidence of thymic or lymphatic state, but in many other conditions where there is increased vagus tone, such as the cases of congenital microcardia described by I. Adler or the gastric neuroses discussed by S. Neuhof, a careful examination by means of percussion, *x*-ray, and blood count will usually fail to reveal this condition. Since there is often a low blood pressure, it is possible that a hypoplasia of the adrenal system, either congenital or acquired, is responsible. It would be more than likely that this would be accompanied by primary or secondary dysfunction of other members of the endocrine system; at all events, it would be an extremely interesting piece of research for somebody

to test out such cases carefully with the Abderhalden serum reaction.

In Basedow's disease, a careful study of the symptoms will often enable us to tell whether there is an increased vagus or sympathetic tonus, and in a general way two different types of the disease may be distinguished. The sympathetic cases show a greatly increased heart action with comparatively less marked subjective symptoms and the blood pressure is often high. Among eye symptoms there is pronounced exophthalmos with positive Moebius sign, negative Graefe and Stellwag, dry bulbs, and infrequent winking. The thyroid gland is apt to be large and vascular but salvation, sweating, and diarrhea do not occur. Other symptoms are falling out of the hair, inclination to fever, and an increase of the eosinophile cells in the blood. The Löwi phenomenon is generally positive and there may be alimentary and adrenalin glycosuria and a refractory behavior toward pilocarpine. The vagotonic cases show only a moderate tachycardia, sometimes even a bradycardia, but with pronounced subjective symptoms on the part of the heart, which may be intermittent in character. The blood pressure is more apt to be low, the exophthalmos and Moebius sign are absent or poorly marked, but the Graefe and Stellwag symptoms are usually definite, with increased lacrymation and frequent winking. The thyroid is often relatively small and hard, there is apt to be salivation and profuse sweating with diarrhea and a tendency to gastric disturbances. The blood gives no evidence of an eosinophilia, metabolic tests show an increased fat and carbohydrate tolerance. There will be no glycosuria after the injection of adrenalin, but pronounced reaction is seen after 1/10th grain pilocarpine. Aschner's phenomenon (pressure on the eyeball leads to a slowing of the pulse) is present, but not if atropine is first injected. Less common symptoms are pigmentation, marked myasthenia, and cachexia. Kocher also speaks of thickened subcutaneous tissues and a peculiar habitus and gait, suggesting double, congenital luxation of the hips. Where vagotonic symptoms are pronounced, it is important to search for enlarged glands and a hypertrophied thymus, though it must not be forgotten that most likely even microscopic traces of the latter may cause mischief. An hypertrophied thymus is sometimes disclosed by the *x*-rays, sometimes by percussion in the first and second interspace to the right and particularly to the left of the sternum, especially if the patient rests on his stomach (Jacobi).

Simple as this classification may seem, it is more common to find some vagotonic and some sympathicotonic symptoms present at the same time, very often so that it is impossible to tell to which class the patient really belongs. A true antagonistic action between thyroid and thymus is therefore doubtful and it is more likely that both glands, when hyperplastic, elaborate both vagotonic and sympathicotonic poisons. The pure vagotonic or thymic cases are certainly rare; thus Halsted reports only 20 out of a total of 500. He describes them as "those terrible cases where there is a rather hard not very much enlarged or vascular thyroid, great emaciation, dilatation of the heart, sweating, diarrhea, relatively slight exophthalmos not excessive tachycardia, and often a peculiar, greyish-bronzed skin." That they form a far more serious condition than the Basedow that we are accustomed to see is evident from the following figures: Fatal cases from intercurrent disease 44 per cent., from the disease itself 82 per cent., and after operation 95 per cent.

The complicated relationship between thyroid and thymus is well summarized by Matti[8] whose conclusions probably represent the general consensus of opinion on this matter at the present day. He states that "the hyperplastic thymus in Basedow's disease is no accidental finding but the enlarged organ actively participates in the symptom complex. It cannot be regarded as essential to the post-mortem findings, though in all probability the great majority of all Basedow cases show it. In all likelihood, the substances secreted by the thyroid are rendered more potent by the thymus, though the latter alone may elaborate substances which poison the heart or cause damage indirectly by the concomitant hypoplasia of the adrenal system. The frequency with which an enlarged thymus is found does not necessarily speak for a deleterious action of this organ since its pathological function need not be in proportion to its size. There is no doubt, however, that a large percentage of those who have large thymus glands die of the disease or after operation. The exclusive thyroid etiology of Basedow's disease is therefore no longer tenable for the thymus also plays a rôle which may be so pronounced that it actually dominates the clinical picture. This is proven conclusively by recent surgical reports. It is not possible even in the presence of such vagotonic symptoms as pronounced subjective cardiac disturbances, profuse sweats, disturbances of digestion, diarrhea, and marked myasthenia to conclude that a hperplastic thymus is present. Even the pilocarpine and adrenalin tests have only a restricted value. The only really reliable evidence can be obtained by percussion and the *x*-rays. An enlarged thymus is no contraindication to an operation; on the contrary, a primary resection of the thymus is to be considered where a decided hyperplasia can be made out and the thyroid clinically shows only slight change. The 20 per cent. failures reported from some surgical clinics even after extensive thyroid resection certainly would seem to show that the thymus and probably some of the other ductless glands play an important rôle in the pathogenesis of Basedow's disease."

An ingenious attempt has been made to solve many of the mysteries surrounding the relationship of the thyroid and thymus to Basedow's disease in a very recent article by C. Hart.[9] This author believes that a congenital abnormal constitution lies at the bottom of most cases. Hyperplasia of the thymus is but one of the symptoms of this lymphatic constitution; it will induce a functional hyperplasia of the thyroid possibly in order to paralyze the toxic products of the thymus. This compensation exceeds the requirements and finally results in pathological changes in the secretion of the thyroid. In other words, congenital thymo-lymphatism will lead to compensatory hyperthyroidism and this to dysthyroidism with the symptom-complex of Basedow's disease. This theory will easily explain the thymic and the mixed cases. Hart does not deny that there are purely thyroid cases where not the slightest pathological change can be found in the thymus. In these there is no abnormal constitution but the disease is the result of acquired, not congenital, changes in the thyroid alone or of abnormal function of other glands in the system, such as the ovaries. They usually develop later in life (as during the menopause) and run a more benign course.

Conservative as the conclusions of Matti are and

plausible as the theories of Hart seem, they are not entirely shared by the greatest authority on the thyroid, Kocher.[11] This author is rather inclined to minimize the importance of the thymus in Basedow's disease, though in his autopsies there were also frequently lesions in the thymus, lymphatic system, suprarenals ovaries, and occasionally in the pancreas. He lays rather undue stress upon the fact that thymus medication will improve many cases of the disease even where a large thymus is present. He also found that the thymus shadow disappeared in fully 75 to 80 per cent. of the cases after thyroidectomy and even where it persists there may be a perfect cure. The myasthenia upon which so much stress has been laid by those who believe in the vagotonic theory often disappears after strumectomy. Even where pronounced other vagotonic symptoms are present, there need be no changes in the thymus or this organ may be enlarged but the seat of a fibrosis which would preclude the possibility of an elaboration of toxic secretion. The diagnosis of Basedow plus thymus hyperplasia of an active nature is thus extremely difficult, but Kocher finds that periodic cardiac disturbance in the form of dyspnea, oppression and a rapid and irregular pulse together with cachexia, marked fatigue, thickened subcutaneous tissue and a peculiar habitus and walk, suggesting double, congenital luxation of the hip are rather characteristic. But all these symptoms are curable by strumectomy.

In the treatment of dysthyroidism and Basedow's disease we must consider the medical and surgical aspects and the effect of the *x*-rays. All except the advanced cases should be treated medically at first even though we have no drug as yet that always exercises a specific effect. The older drugs, such as quinine and ergot are sometimes of value, but more can usually be expected from the phosphate and glycerophosphate of soda if given in sufficiently large (half dram) doses. Heart stimulants, such as digitalis and strophanthus, which would normally slow a rapid pulse have no effect upon the tachycardia unless there is actual myocardial insufficiency. We rarely can get along without nerve sedatives and for the milder cases, the modern valerian preparations and the bromides will be sufficient, while the severer cases often require opiates. Preference should be given to the less habit-forming ones, as codeine and dionin, but often the same results can be accomplished with veronal and medinal. The most recent veronal derivative, luminal if given in small doses (one grain) often exhibits a specific effect upon the tremor, nervous excitement and abnormal psychic state and can be recommended most highly. Thymus and ovarian extract and even pancreatic extract have been given with doubtful results. Rodagen, the dried milk of thyroidectomized goats, in gram doses is preferred by some, but in my cases it has proved disappointing. The Antithyroidine of Moebius undoubtedly is effectual in alleviating most of the distressing subjective symptoms and also has a decided beneficial action upon many of the objective signs if given in sufficiently large doses. The experimental evidence is, however, against this. Thus, Sonne[12] gave some patients with Basedow's disease the blood of thyroidectomized animals and others the blood of normal animals. After both an equal percentage of improvement could be noted. He also tried to create an artificial hyperthyroidism in animals by feeding them thyroid and found that their symptoms were influenced in the same way by normal serum as by antithyroidine. It must be stated, however, that it is hardly possible to produce hyperthyroidism in animals by feeding them even large amounts of thyroid. The real value of every medication we order is so much obscured by the dietetic and hygienic measures that we feel it our duty to recommend that it is very difficult to come to any conclusion as to the effect of any given drug. Since it is possible to remove the thymus in animals without serious harm, I have requested one of the German firms to prepare for me an antithymus serum and also an antiovarian serum, to be used in conjunction with the antithyroidin, but owing to the war these plans could not be carried out. The preparation of Beebe usually does more harm than good and we can only warn against it. There remain then as reliable therapeutic agents for the internist only dietetic and hygienic measures. Many of the patients will improve spontaneously without medication, others get well on a lactovegetable diet, a rest cure with forced feeding and hydrotherapy with only such drugs as the symptoms may require. In women we often see considerable improvement during pregnancy, probably because the excess of thyroid secretion is better made use of during this time. Sanatorium treatment, as a rule, is not to be recommended since it is better for the patient to stay under the strict control of the family physician who can best determine when the time has come for further treatment.

It cannot be sufficiently emphasized that every case treated medically should be under constant control for the result can never be foretold. A decided Basedow, even in the presence of vagotonic symptoms and a marked mononucleosis and eosinophilia may get well in this way or else so much improvement will set in that the patient is perfectly comfortable and satisfied. On the other hand, a much milder case, under the same regime, may develop into a full-fledged Basedow with fulminant symptoms, sometimes without any apparent cause. By constant medical supervision, is meant particularly a control of the weight and of the heart action, wherever feasible with the most modern methods. Where improvement is not soon evident or where the patient's means do not permit of a lengthy and perhaps expensive treatment, further measures will have to be considered.

The Roentgen rays were first employed in Basedow's disease by two Americans, Mayo and Beck. They may be used after a conservative operation such as ligation of the vessels or in place of an operation, though many surgeons are of the opinion that a subsequent operation will then be more difficult. Among recent writers, Sielman[13] reports 4 complete cures, 7 marked improvements, 8 slight improvements, and 2 failures out of a total of 21. The exophthalmos disappeared completely in 5 cases. Mannaberg and Sielman also recommend that the ovaries be treated, but v. Graff[14] warns against this, for he and Novak have seen Basedow disease develop directly after Roentgen treatment for myoma. The same difference of opinion exists as to the thymus: Halsted has employed the Roentgen rays and radium with good result, while Klose, one of the most thorough students of this gland states that it is extremely sensitive to active rays of any kind so that evidences of degeneration may already be found after one instantaneous exposure.

What then is the effect of the newer research on the surgical treatment of thyroid hyperplasia? Except in the intensely thymotoxic cases, I think, we can advise a ligation of the superior thyroid ves-

sels with a clear conscience in all instances where improvement by other means is not satisfactory. The chief question is what to do in those cases where this operation proves inadequate. Undoubtedly, a hemistrumectomy is indicated, for, according to Halsted, there are 60 per cent. approximate cures after this operation, though in 70 to 80 per cent. there remain some symptoms of thyroid or thymic hyperactivity. In most cases, however, all these symptoms except, perhaps, the mononucleosis will disappear if as much as possible of the second lobe is removed. Thymectomy, as practised first by Garre and Sauerbruch, and in this country by Halsted would thus be limited to a small number of cases were it not for the fact that the post-operative mortality is apparently lower after the combined operation. In the words of Halsted, "the combined operation gives better results than the thyroid operation alone and striking is the relative absence of a reaction." It is said that by means of thymectomy we can avoid those unexplained deaths which have been seen after so slight an operation as ligation of one thyroid vessel under local anesthesia, lasting 10 minutes. In all probability then we are serving our patients better if, after medical treatment, the *x*-rays and ligation have failed, we remove as much of both organs as we can. Some authors are even inclined to practise thymectomy alone, stating that even the purely thyroid symptoms will disappear as readily as after thyroidectomy. Hart however has pointed out that thymectomy alone may not bring the desired relief if the changes in the thyroid, induced by the thymus are already so far advanced as to be permanent. In these cases only the combined operation will bring about a cure. From all descriptions, thymectomy seems to be a simple operation which can, if necessary, be done under local anesthesia and without resection of the sternum. It is best, however, to prepare these patients for a few days by giving them adrenaline and pituitrin, calcium salts, and, if necessary, heart stimulants and letting them rest quietly with an ice-bag to the heart.

We can only conclude that as a result of experimental research, the Abderhalden serum reaction and the truly remarkable successes reported by the surgeons after thymectomy, it is probable that, in all but a small percentage of cases of dysthyroidism and Basedow, whether vagotonic or sympathicotonic in type, the thymus shows dysfunction, the result of a congenital, hypoplastic constitution. Only in this way can we explain the persistence or recurrence of symptoms after even radical operations on the thyroid and the sudden deaths after operation. By taking the thymus into consideration, we can promise more speedy cures and also lower considerably the post-operative mortality. Cases without thymic involvement are in the minority, are usually acquired later in life, and run a more benign course. If not cured by medical means they will usually yield readily to operation on the thyroid alone, though it is possible that other ductless glands play an important rôle which may influence the surgery of the future.

THE TREATMENT OF EPILEPSY FROM METABOLIC DISTURBANCES IN ADOLESCENCE.

By TOM A. WILLIAMS, M.B., C.M., EDIN.,

WASHINGTON, D. C.

CORRES. MEMB. SOCS. OF NEUROL. AND PSYCHOL. OF PARIS; PROFESSOR OF CLINICAL NEUROLOGY AND PSYCHIATRY, HOWARD UNIVERSITY; NEUROLOGIST TO EPIPHANY FREE DISPENSARY, FREEDMEN'S HOSPITAL.

Incorrect Treatment.—As it appears that toxins are responsible for the convulsive attacks in the cases I have described (*Interstate Medical Journal and Review of Neurology and Psychiatry*, April, 1915), two courses are open to the physician.

One of these is to favor elmination of toxins. This has been done by stimulating the emunctories: diuretics are given to increase excretion by the kidneys, purgatives to increase elimination by the bowels, diaphoretics and baths to stimulate the skin; active exercise is prescribed to increase oxidation and favor the elimination of carbon dioxide by the lung; or an attempt is made to promote metabolism in general by various forms of electricity.

None of these procedures, except indirectly, attacks the cause of the disease, and so none of them can be recommended except as an adjuvant. This is particularly the case regarding purgatives; for many of these are tissue poisons, which are absorbed to some extent unless given in drastic doses, which, of course, is not permissible, as it entirely prevents assimilation of food. Magnesium salts, so often given, are when absorbed severe neuromuscular depressants. But even the alkaline aperients are not unobjectionable, because they interfere with the osmosis which is the foundation of normal assimilation. Our efforts, on the contrary, are to be directed towards the establishment of a metabolism as near the norm as possible for the patient, and I believe it irrational to interfere with this at its very inception in the intestine, by any purgative, no matter how mild.

Still more to be condemned in the treatment of convulsive tendencies is the attempt to suppress the effect of the toxins by counteracting drugs, such as aconite, belladona, nitrites, etc., of which the iodides are the most familiar example. This procedure is not only unsuccessful, because it still further disturbs metabolism, but it draws the physician's attention away from the main point. Even more to be condemned is the masking of symptoms by sedatives or anti-spasmodics such as bromides or essential oils, or by hypnotics and narcotics such as chloral, morphine, cannabis indica, alcohol, or preparations of coal-tar. Equally reprehensible is the contrary procedure of stimulating the body reactions by strychnine or by the caffein class of drugs.

Correct Treatment.—(1) As the toxins responsible for the patient's ill health occur in consequence of an incapacity to metabolize an amount of protein which the average individual can take with im-

punity, the most important feature of correct management is the limitation of the protein intake so as not to exceed the patient's maximum. As it has been shown (Chittenden) that the physiological minimum for health is not 100 grams, as Vogt supposed, but only about 50 grams per day, there is no physiological inconvenience in so limiting the protein intake.

(2) At the same time, energizing material must not be insufficient; so that the limitation of protein must be compensated by an increase of the carbohydrate and fatty constituents. These I generally permit the patient to eat without limitation; for experience has shown me that the appetite does not exceed body tolerance for such substances, in the absence of diabetes or pituitary disease.

(3) The third most important feature of the treatment is the giving of the vegetable salts, * * * This should be in the form of fruits and vegetables, so as to furnish inert bulk by fiber and cellulose. * * * in an amount amply sufficient for free activity of the secretions.

These recommendations are embodied in the "model diet" given to each patient with certain modifications which the case may require.

It is very unwise to give to patients, and especially to young persons, a rigid or lengthy dietary; because neither will be followed. The important point is that the patient grasps the principles by which his dietary should be regulated *by himself*. As these are very simple, he can then apply them to any menu placed before him; and thus with very little difficulty, choose what will be beneficial.

The principles are:

1. To take not over 2 ounces of dry protein, which means not over ten ounces of nitrogenous food in the natural state, which includes, eggs, milk, cheese, the flesh of all animals, birds, and fish, nuts, peas and beans, and to a less degree bread and cereals.

2. To eat abundantly the starchy and sugary substances, from which to obtain heat and energy.

3. To eat freely of fiber and cellulose in the form of vegetables and fruits so as to prevent constipation, which would favor the absorption of poisonous substances. They also prevent stagnation of lymph in the tissues on account of their saline character.

4. To favor oxidation by brisk exercise* (the nature of this is gone into in detail with each patient according to circumstances).

The Model Diet.—While dressing, five ounces of hot water containing 5 to 10 grains of sodium bicarbonate. Half an hour later, breakfast of a large plate of fruit and milk or cream, followed by abundant cereal and milk, with bread and butter. No meat, eggs, or fish. Wait five hours. Dinner, not more than four ounces of meat or fish, which must be quite fresh, a *very large* plate of green vegetables, potatoes sparingly, and preferably nothing more than a taste of sweets. The evening meal, five hours later, may be a repetition of the breakfast, but succulent vegetables may replace the fruit, and macaroni or a similar dish may be substituted for the cereal. Thirst and hunger between whiles may be satisfied by water and fruit about one hour before a meal or during the night. The purins are avoided, so that meat juices are abstained from, and soup, which may be taken at dinner or supper, must be made entirely of vegetable food. Alcohol is forbidden, even as beer or wine. Tea, coffee, cocoa, and kola must be abstained from, as besides being closely allied to the xanthin bodies, they are toxic to the nervous and circulatory systems.

Gradually this diet is added to, an occasional egg being given at breakfast or supper, and the patient very soon learns what suits him best. Some culinary ingenuity is needed to give variety to a diet which at first appears monotonous. In this respect the tastiness of well prepared whole wheat bread is a great gain.

*Of course proper baths are not omitted.

THE NAGELSCHMIDT MODIFICATION OF THE KROMAYER QUARTZ LAMP IN THE TREATMENT OF DISEASES OF THE HAIR AND SCALP.*

By RICHARD W. MÜLLER, M.D.,

NEW YORK

Hitherto the treatment of premature or senile baldness has been of very little effect. No matter what remedies, local, internal, or mechanical have been employed, the result has been far from satisfactory, and the number of young and old men partially or totally deprived of their hair has increased from year to year until now it seems as if half the male inhabitants of industrial centers, and even of small towns and villages, show varying degrees of baldness.

Not less has the female sex suffered increasingly from an insufficient supply of hair, it being either too thin or too short, seemingly as if the further development of the hair had been arrested and the life of the papilla were extinct or, at least, its productive activity suspended.

Many of the fair sex anxiously complain of the loss of their hair in large quantities long before middle age has been reached, of increasing patches of baldness, of partings growing wider and wider, making them appear bald; and last, but not least, of having the baneful gray hairs appearing among their black or blond tresses in ever-increasing numbers, giving them the appearance of senescence long before the time when gray hair would naturally be expected and gracefully accepted.

The medicinal methods used from time immemorial up to the present date have been the local employment of various lotions, fats, salves and "tonics," and the internal administration of iron, arsenic, strychnine, and other restorative medicines familiar to medical practitioners and to the public. For mechanical assistance, frictions, massage, and vibratory movements were universally employed. Large glass vessels, cuplike in shape, fitting the upper part of the head and provided with airpumps to render them airtight, came into use some years ago and were widely advertised as a universal remedy for baldness. They were used by many, but the number of bald men was not diminished. By means of these glass vessels, the air was exhausted above the scalp and suction exerted upon the blood-vessels supplying the hair-growing apparatus with nutriment. This action was believed to stimulate the papillæ to renewed action, and it was hoped that the hair would be produced once more, in spite of years of cessation of growth.

For thin and insufficient hair, it is now, and has been for some time, the favorite method to submit to the operation of masseuses, who go from house

*Read before the Medical Association of the Greater City of New York, February 15th, 1915.

to house to give their customers, mostly women, frictions and manipulations of the scalp with more or less vigor, according to the measure of enjoyment these customers derive from the process and their hope of cure.

Even dietary measures have been resorted to in order to improve the growth of hair: Toast, oatmeal, raw milk, raw eggs, carrots, soups made out of the bones of animals, and gelatin, are considered by even so high an authority as Prof Max Joseph of Berlin, as particularly suitable articles of food for those who would grow hair on a recalcitrant and arid scalp, and to have proved of much benefit to many.

For the cure of early "graying" of hair, no remedies have, to my knowledge, ever been seriously considered. The most modern work on "Kosmetics" by Prof. Max Joseph has nothing to advise but artificial coloring, and he gives his approval to dyes which are both effective and innocuous, namely, those containing salts of silver and of pyrogallic acid.

It is an old experience in the history of medicine that whenever a malady has been found that is difficult to improve or overcome, a great number of remedies and remedial measures are suggested, but alas, none has proved very effective in the treatment of the hair. With this need in mind, the dermatologists of to-day have not neglected to apply every remedy that offered any hope of relief. No sooner were the Roentgen or *x*-rays discovered than they were tested for their influence upon the growth of the hair; but aside from enabling us to remove objectionable and superfluous hair from the face, and to destroy the fungus of favus and ringworm, no remarkable effect has been attained thus far, and certainly no stimulation of growth. Neither has the Finsen light been of much use in the treatment of affections of the scalp; or, if it has, nothing has been reported to the profession which might be an incentive to the use of that powerful light.

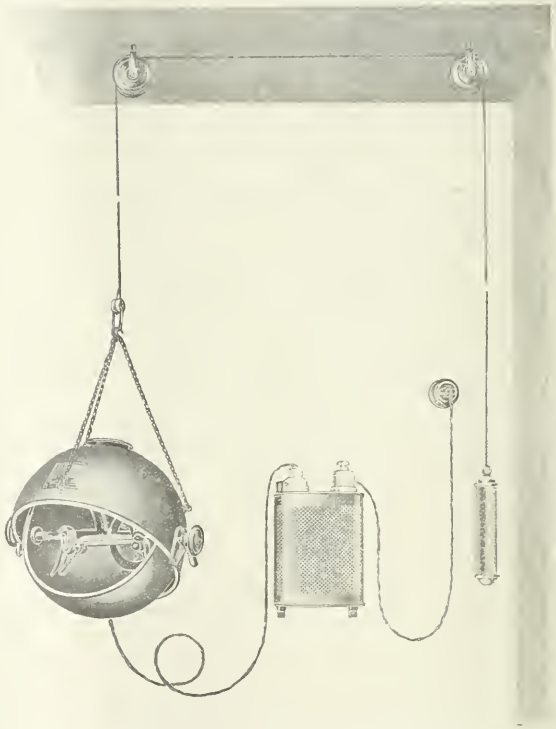
Kromayer's quartz lamp, constructed for the purpose of treating irritating and itching skin affections, was the first successful agent in the field of constructive therapy and effected numerous cures of ringworm and alopecia areata.

The next successful agent in the treatment of these diseases of the hair and scalp was the D'Arsonval-Tesla high frequency current. This received scant attention at first, but was later championed by Chatalain in his "Maladies de la Peau," 1910, Allen, MacKee, Vassilides, Keating-Hart, Fontana, Brocq, Belot, and Paul Gastou. I, myself, used this method of treatment for three years and was well pleased with its efficacy. It has, however, the serious disadvantage of requiring innumerable applications, at frequent intervals. Besides, there were many failures.

In 1913, Nagelschmidt published his modification of the Kromayer lamp and blazed a new trail in the domain of hair and scalp therapy. It may not be amiss at this point to outline briefly the essential features of this lamp.

The Nagelschmidt modification of Professor Kromayer's quartz lamp or "miniature Alpine sun (see the illustration) may be described as an electric arc in mercury vapor, in a quartz burner, enclosed in a spherical lamp body mounted either on a stand with a tripod base or in a hanging device, and provided with a rheostat. The burner consists of a shallow arch-shaped tube of translucent quartz glass three and a half to four inches long and placed with the convexity upward. At each end is a small reservoir of mercury in a cylindrical tube which joins the arch-shaped tube in T-fashion. The electrodes in lead covered wires, respectively red and white for the two poles, lead into the mercury chambers. To provide against overheating, each end of the two mercury chambers carries a fan-shaped series of metal plate or lamellæ, which diminish the heat by radiation. This is more practical than the water cooling device of the Kromayer lamp. Needless to add, the quartz cylinder contains mercury vapor, but no air.

Second, the lamp body, which contains the burner. This is a large hollow sphere, preferably of aluminum, which is either suspended from the ceiling or is fastened to an upright rod on a tripod, facilitating its transportation from and to any part of the office. Two rods fixed horizontally to an arm on the inside of the lamp-body carry the burner, which can be tilted by a wheel outside. A current indicator shows whether the connections are correct. A sliding door on each side enables the aperture to be varied at will. A folding screen of green cloth closes the lamp from underneath. The chimney can be opened vertically or horizontally; the latter facilitates breathing the ozone.



Third, the rheostat. This is attached to the

column of the stand in the tripod type of lamp-holder. The hanging lamp has the rheostat attached to the wall beneath it. Mounted upon the rheostat is a plug of porcelain to which the lamp is connected, and a switch is provided for turning the current on and off.

The size of lamp originally employed requires a four-ampere, 90 to 120-volt, direct current, and gives about 1500 candle-power light. There is another lamp which requires a 200 to 240-volt direct current of 2½ amperes, and gives 2000 candle-power.

Now, as to the application of the treatment. Dr. Nagelschmidt reports a series of 200 cases that have been treated by him in succession for alopecia areata, alopecia seborrhoica, prematura and senilis, and seborrhea capitis. It is to be noted that these cases were not selected for the purpose of showing the efficacy of his modification of the Kromayer lamp, but are consecutive cases from 1907 to 1913, accurately tabulated and controlled, and published in his monograph in 1913. They consist of 132 cases of alopecia areata, 53 cases of alopecia seborrhoica or prematura, and 22 cases of total baldness. The 53 cases of alopecia seborrhoica or prematura were all cured, without exception. Not alone were the itching and pain removed, but all the scales disappeared, their hair was regenerated, and new normal hair appeared in place of the old hair which had fallen out in the course of the disease. Of the 132 cases of alopecia areata, 80 per cent. were cured, 16 improved, and only 8 remained unimproved. Furthermore, 22 cases of total baldness were treated and all of these were cured except six cases—of which some failed to return for treatment, others were somewhat improved, and only a few were not benefited at all.

Some of the astonishing results of the Nagelschmidt method of treatment may be mentioned. In one case of complete baldness due to seborrhea, Dr. Nagelschmidt applied the customary treatment with local remedies, tinctures, and ointments, as well as massage and faradization, to one-half of the scalp and the rays of the quartz lamp to the other half. After a time, an excellent growth of hair had been produced on the half that had been treated with the lamp, whereas the other half remained as bald as before.

Furthermore, in many cases he has succeeded in bringing out new hair of the normal color of the person treated—blond, red, black, or brown—in place of the gray hair, and has thereby given the patient a decidedly rejuvenated appearance, much to his or her delight.

One can well see how Nagelschmidt, filled with enthusiasm for the light therapy for baldness and other diseases of the scalp, should condemn nearly all other methods in use for the cure of these troubles. Since my three years of dermatological study abroad, during the years 1907, 1908, and 1909, it has been my custom to return there for a few months of study every year. I have been enabled, especially in Doctor Sabouraud's clinic in Paris, and Professor Joseph's clinic in Berlin, to observe the progress of the treatment of scalp and hair diseases. For a long period, the progress, so-called, was but the stationary routine of former years, and the patients were but little benefited after they had reached advanced stages. With the introduction of Nagelschmidt's lamp, we have reason to believe that the picture will change and that those hitherto resistant and barren cases will offer a fertile field of cure under the new therapy.

It was my good fortune to observe the application of the treatment, for a period of six weeks last summer, in Nagelschmidt's clinic in Berlin, and I was much impressed by the results achieved.

Since my return at the end of October, I have had the opportunity of applying the treatment in my own practice in about 60 cases. Naturally, the time has been too short to enable me to make any definite statements as to the results obtained, but I feel that it is not amiss for me to say that my experience thus far has borne out my observations while abroad and my hope of its successful use here.

My procedure is as follows: The diagnosis of the scalp condition is made by the usual inspection. In cases of falling hair, the rate of loss is determined by a daily count, for three successive days, of the number of hairs lost during the daily combing, and by noting how many of these hairs are long and how many short. The long hairs are old and the short hair is young. Patients who are losing relatively many short, young hairs present a poor prognosis. The sittings for treatment are so timed that about one furrow or "part" of the scalp is exposed to the rays at one time, the remainder being protected. As much is done at one sitting as is convenient. The interval between treatments must be long enough to allow for the subsidence of whatever reaction follows the application of the rays. The remainder of the patient's skin must be carefully protected—especially the ears, face, and arms—against damage from the rays, and this is done by covering those areas with pieces of black cloth.

I shall not include any statistical data of my own in this paper, but shall do so in a future publication. Generally speaking, however, I will state that in the Nagelschmidt treatment we have found a method for treating the scalp and for the regeneration of hair hitherto considered hopelessly and permanently lost, that will prove little short of revolutionary in this field.

It is wholly in the order of things that a new method of treatment is received with various grades of acceptance, ranging from incredulity (Felix Pincus), through lukewarmness (Blashko), to enthusiasm (Drs. Brieger, Meyer, Schmidt). It is inevitable that some will scoff, and one hopes that some will acclaim.

In my forthcoming translation of Nagelschmidt's monograph, "Loss of Hair and Its Treatment by the Quartz Lamp," many of Nagelschmidt's individual cases are described in detail, with case histories and photographs showing their condition before and after treatment. These are most convincing.

Unfortunately, the method is not one that can be adopted in general practice, because the apparatus is expensive, the technique must be studied, and the treatment—though given in each case but once in three weeks—is time-consuming, usually extending over one or two hours and occasionally much longer. The point I particularly wish to emphasize, however, is that this treatment gives us the most definite and hopeful means yet known of ameliorating a condition which has hitherto proven obstinately refractory, and has been a source of embarrassment and discomfort to its unfortunate possessor.

Gastric Ulcer and Intercostal Pains.—G. Cavina points out that in rare instances gastric ulcer with or without adhesions is associated with zones of cutaneous hyperesthesia or of neuralgia in the intercostal spaces. —*Rivista Critica di Clinica Medica.*

FURTHER OBSERVATIONS ON THE PRODUCTION OF STERILITY BY THE ROENTGEN RAY.

By FRANK B. GRANGER, M.D.,

BOSTON, MASS.

INSTRUCTOR IN ELECTRO-THERAPEUTICS, HARVARD GRADUATE SCHOOL OF MEDICINE; PHYSICIAN TO THE DEPARTMENT OF PHYSICAL THERAPEUTICS, BOSTON CITY HOSPITAL.

In a paper read, September, 1907, before the American Electro-Therapeutical Association, I gave a résumé of the literature on the production of sterility by the Roentgen ray and cited three cases, one of which was treated in May, 1905—only three months after Brown and Osgood had reported that Roentgenologists were liable to be rendered sterile by their occupation. At that time I pointed out that this had been forecast by the work of Albers Schoenberg on guinea-pigs, where sterility had been produced by 370 minutes' exposure to the Roentgen ray. I then considered the experimental work on seeds and eggs and showed that their fertility was influenced by the ray.

Pathologically the seminal epithelium seemed to have been destroyed in the male with no diminution of the internal secretions and no atrophy of penis or seminal vesicles; while in the female the results in the ovary were sterility, and the appearance of all the symptoms, which follow complete ovariotomy. The cases which I reported at that time were:

Case I.—A woman with a large uterine fibroid which showed after hysterectomy, although she had had fifty-nine treatments with *x*-ray exposures, no evidence of destructive action on the ovaries per se.

Case II.—A man, who on account of insanity in his own as well as in his wife's family, desired to become sterile, and who showed numerous actively motile spermatozoa, was rendered sterile after thirty exposures. Up to the twentieth exposure no influence was noted on the spermatozoa, but from that time to the thirtieth rapid changes took place. This case was examined at frequent intervals and the following note was made in my case report: "On May 14, 1913, nearly eight years after the last *x*-ray exposure, there is still complete absence of spermatozoa, and there had been absolutely no diminution of sexual potency or desire." In May, 1915, there was a return of active, motile spermatozoa, and a vasectomy was performed by Dr. John Cunningham.

This case is instructive, as it bears out to the letter the conclusion of my former article, namely, "While it is not safe to draw conclusions from insufficient data, yet from the cases reported, and my own, we may conclude that while the *x*-ray can and does produce sterility, yet the quantity needed to produce such a result is much greater than one would suppose, reasoning from animal experimentation and from the hysterical warnings of certain writers. We may also agree with Laquerrière that while a patient may be rendered sterile by the *x*-ray, either by direct or indirect radiation, that such sterility may not be permanent, and that a condition of complete sterility continuing through a number of years is compatible with perfect virility and genital competence."

Before Case II came to this timely—or untimely—end, I sterilized another case which is now reported for the first time.

Case IV.—Mr. V., 45 years old; history of insanity in the family; married late in life a lady with a badly compensated cardiac lesion. In view of these facts it seemed legitimate to produce sterility. While in former cases I had used an induction coil, with a mercury turbine interrupter, using three ampères in the primary, in this case I employed a large high frequency coil, with a tube giving out No. 4 rays Benoist. In all seventeen exposures were given, averaging fifteen minutes, over a period of three months. The exposures were made alternately, anteriorly, and posteriorly, on the scrotum; some tanning occurred but no dermatitis ensued. After the twelfth exposure the spermatozoa became misshapen and less motile. After the seventeenth there was complete azoospermia. After a period of eighteen months there has been no change in the picture.

In view of Case No. II I should advise either an occasional course of the Roentgen rays until his wife has passed the menopause, or a vasectomy.

In conclusion let me add that such results hold out much encouragement for those Roentgenologists, who, pioneers in our work, unwittingly become sterile and for these newer workers who, dependent upon, I am afraid, inadequate protection from the powerful rays of the Coolidge tube, will suddenly find themselves sterile, and for those, who in their zeal for fluoroscopy will find that the selective action of the Gamma rays will penetrate the protection offered by the modern Roentgenoscopes and effect the seminal epithelium, just as surely as it has done in the past. And finally, when we wish to ensure permanent sterility, vasectomy is surer than the Roentgen ray.

REPORT OF A CASE OF RUPTURE OF THE PROSTATIC URETHRA.*

By S. WILLIAM SCHAPIRA, M.D.,

NEW YORK.

ADJUNCT PROFESSOR OF GENITO-URINARY SURGERY, FORDHAM UNIVERSITY, SCHOOL OF MEDICINE; VISITING G. U. SURGEON, SEA VIEW HOSPITAL AND SYDENHAM HOSPITAL; ASSISTANT G. U. SURGEON, CITY HOSPITAL AND WORKHOUSE HOSPITAL.

G. B., aged 14, entered Sydenham Hospital May 7, 1912, with a history of having been run over by an automobile on May 6, 1912. He was taken to Harlem Hospital but refused operation and was sent home that day. The patient entered hospital with a diagnosis of rupture of the bladder. Superficial examination showed distention and ecchymosis of the abdomen, infiltration and ecchymosis of the penis, perineum, and scrotum. A metal catheter inserted through the urethra apparently into the bladder brought only a few drops of blood.

Suprapubic incision showed a full bladder; oozing of blood on the outside of the bladder was stopped by hot gauze sponges. The bladder was opened and a large quantity of clear urine escaped followed by some bloody urine and clots; the finger in the bladder could not feel the end of the metal catheter. Pushing the finger into the internal meatus showed the prostatic urethra entirely severed from the bladder, and after some manipulation the tip of the metal catheter was found some distance below; as all of the tissues were greatly distended and infiltrated, a large suprapubic drain was inserted and left in place until May 15, when all the infiltration had disappeared. After removal of the suprapubic drain, the pubic bones were found to be separated and the left was at least one inch below the right. A soft rubber catheter was introduced through the urethra into the bladder (which was easily accomplished, but was impossible at the time of operation) and the catheter drainage was maintained for over two weeks, the catheter being changed and the bladder irrigated daily at first, and every two or three days later. The permanent catheter was removed May 29, when the suprapubic wound was nearly closed. On June 3 the suprapubic incision was closed.

The patient was discharged from the hospital June 4, 1912, in perfect condition, except the pubic bones were not entirely approximated, but were approximating quite rapidly. The patient had a course of sounds for about three months afterwards and was then discharged by his family physician.

The patient called again November 1, 1914, complaining of frequency of urination by day and very narrow

*Read at the Section on G. U. Surgery, N. Y. Academy of Medicine, Feb. 17, 1915.

stream. The urine was perfectly clear and the pubic bones were in perfect apposition. The sound went to the prostatic urethra where it met with a very hard obstruction, and on repeated sittings even a filiform bougie could not be passed into the bladder. A diagnosis was made of stricture of the prostatic urethra.

Operation, November 6, 1914.—Perineal section was performed and a hard fibrous ring was removed from the prostatic urethra. A perineal tube was inserted for drainage and a large catheter passed through the urethra to the neck of the bladder. On November 9 the perineal tube was removed and the urethral catheter pushed further into the bladder and retained by adhesive plaster for drainage and for the purpose of keeping the urethra dilated, the bladder being irrigated daily. The catheter was removed November 19. The patient voided urine the same day and was discharged from hospital November 20, 1914.

From a study of this case one may formulate the following conclusions:

1. Diagnosis of rupture of the bladder or prostatic urethra is at times very difficult or impossible.

2. Traumatic injury to the pubes causing rupture of the urethra and separation of the bones as described, will heal kindly, natural process.

3. There is no necessity of approximating the torn ends of the prostatic urethra, so long as adequate drainage is provided to take care of the infiltration.

4. The efficiency of suprapubic drainage in relieving enormous infiltration of penis, scrotum, and perineum, caused by extravasation of urine, is well shown.

5. Stricture may follow rupture of the prostatic urethra months after injury, although sounds have been used for a reasonable length of time.

1847 Madison Avenue.

Medicolegal Notes.

Compulsory Vaccination of School Children. — The school board of the San Antonio independent school district was sued in the Texas courts by the father of infant children to compel the board to admit the children to attendance in the public schools of the district and to restrain the enforcement of a new regulation of the board requiring vaccination of school children. The case was submitted upon the following issues: "(1) Is the danger of an epidemic of smallpox imminent at this time in the city of San Antonio? (2) Do the existing conditions in reference to smallpox constitute a menace to the public health? (3) Is the regulation of the San Antonio school board requiring vaccination of the children reasonably necessary for the preservation of the public health by preventing the spread of smallpox?" The first question was answered in the negative, and the other two in the affirmative. Judgment was entered denying the relief prayed for, and the plaintiff appealed. The chief part of the rule objected to provided that no pupil or teacher should be admitted at the next term of school without presenting a proper certificate from a practising physician showing successful vaccination within seven years; or unless such certificate was on record. Prior to the adoption of this rule the board had a rule requiring vaccination, but containing an exception permitting children to attend if their parent or guardian filed an affidavit that he conscientiously believed that vaccination would be prejudicial to the health of the child. The plaintiff had filed such an affidavit. The Court of Civil Appeals adopted the findings of the jury in answer to special issues Nos. 1 and 2. It was held that as the Legislature did not expressly empower the school board to adopt the regulation in question it must be determined whether it was a reasonable one.

Conditions may change so that an ordinance when applied thereto may be arbitrary, unjust, and oppressive. The power of local bodies to require the vaccination of school children as a condition to their admission to public schools, in the absence of express authority, is dependent upon the conditions existing in the community with reference to smallpox. When an epidemic exists or is imminent there can be no doubt that the power may be exercised. It has also been held that such regulations may be adopted and enforced when smallpox exists in a community, and by some courts the expression is used that such regulations may be adopted when an epidemic is reasonably apprehended. In this case it was found that no epidemic existed or was imminent, but that the existing conditions with reference to smallpox constituted a menace to public health. The court concluded from its investigation of the authorities that it is not necessary for an epidemic to exist or be imminent in order for the school board to be justified in adopting and enforcing the regulation complained of, because if the conditions are such that they constitute a menace to the public health it cannot be said that the board's action was unreasonable and that the want of necessity for the measures has been shown to be "clear, manifest, and undoubted." If existing conditions constitute a menace to the public health, an epidemic is threatened, and it cannot be said that it did not reasonably appear to the board to be necessary to adopt the regulation. If much must be left to the discretion of the board, certainly the undisputed facts in this case and the finding of the jury in response to the second issue showed that the board had not abused its discretion. The rule was held not to be invalid because it did not provide when it was to expire; it would expire automatically when the conditions changed.

The rule also provided that vaccination should be deferred for sixty days upon a certificate from a physician and concurrence by the school physician that vaccination would imperil the pupil's health, and that it might be further deferred upon order of the board of health of the city and the school physician. It was held that this was not an unreasonable provision as conferring upon the board of health and the school physician arbitrary powers, and so was not invalid under Const., Art. 1, Sec. 19, and Const. U. S., Amend. 14, prohibiting the deprivation of life, liberty, or property without due process. Nor did the rule violate the State Constitution, Art. 7, Secs. 1, 3, 5, which declare that a general diffusion of knowledge being essential, the Legislature shall make suitable provision for the support and maintenance of an efficient public-school system and provide a means by which State revenues may be used for school needs.

The rule was not in violation of Rev. Stat., 1911, Arts. 2899, 2900, declaring that all children of school age shall be entitled to school privileges; the statute not depriving school authorities of the right to pass necessary regulations for protection of the health of pupils. The court took judicial notice of the facts that vaccination is, in the common belief, a preventive of smallpox, and that the danger of contagion from smallpox is equally great in theatres, street cars, and other public places as in the schools. But it was held that the school board of an independent school district authorized by the act creating it to make rules for the protection of health may require vaccination to prevent the spread of smallpox, even though the danger from the disease was equally great in places under the control of the city where no such regulation was imposed. Judgment denying relief was affirmed. Zucht vs. San Antonio School Board, Texas Civil Appeals 170, S. W. 840.

Nuisance—Operating Room in Hospital.—Maintaining an operating room in a hospital in such proximity to a neighboring dwelling that the cries of pain emitted by the patients destroy the peace and comfort of its occupants and injure their health is held in Kestner v. Homeopathic Medical & Surgical Hospital, 52 L.R.A. (N.S.) 1032.

Liability of Private Hospital for Negligence.—Action was brought against a hospital, conducted for private gain, to recover damages for negligence in caring for a delirious patient whose death resulted from his jumping from an unprotected, unfastened, and unguarded window in the absence of an attendant. The evidence tended to show that the patient was knowingly admitted to the hospital under an implied obligation that he should receive such reasonable care and attention for his safety as his mental and physical condition required, and that the nurse in charge, at the time of the accident, had been absent for a period estimated by one witness to be less than five minutes and by another to be about an hour. Under this evidence the issue of negligence was held to be for the jury. Judgment for the plaintiff was affirmed.—Wetzel v. Omaha Maternity & G. Hospital Assn., Nebraska Supreme Court, 148 N. W. 582.

THE EXTENSION OF THE VITAMINE THEORY.

It is several years now since Funk isolated from rice polishings a substance which he called vitamine, and which, when administered to patients suffering with beriberi, brought about a cure of the disease. It is the absence of this substance from the dietary which is now quite generally believed to be the cause of beriberi. The success of the researches along these lines in this instance has led enthusiastic investigators to broaden the field of their labors and to extend the same explanation to cover other more or less similar diseases. The extent to which this enthusiasm has led the followers of the vitamine theory is shown in a summary recently published by Watson-Wemyss (*Edin. Med. Jour.*, 1915, xiv, 186). Diseases of the scurvy group are generally conceded to have a close relationship to diet and it is thought that here, too, the pathological condition is brought about by the absence from the diet of "scurvy vitamine." This "scurvy vitamine" is much less resistant to heat and drying than "beriberi vitamine," so that cooked or dried fruits are not suitable for its treatment. Ship beriberi and infantile scurvy are included as being very closely related. From this point the adherents of the vitamine theory broaden out.

First they include pellagra, claiming that vitamines are removed from maize in the process of preparation of the grain for food and that the disease can be prevented and treated by a diet which contains the proper vitamines. Next they include rickets and tetany since these diseases occur in children who are fed on sterilized milk or similar foods and thus suffer from a deprivation of the vitamines which are present in good raw milk. In tetany it is believed that the ingestion of vitamines is necessary for the proper action of the parathyroid and thymus glands. The beneficial effect of cod-liver oil in these conditions is ascribed largely to the vitamines which it is known to contain. Vitamines are capable of stimulating normal growth, therefore may they not play an important part in the stimulation of abnormal growth, that is, tumor formation? It is said that in severe infectious diseases, a purely starchy diet is dangerous in that it may lead to anorexia, cardiac weakness and sometimes even to nerve degeneration. These are looked upon as symptoms of beriberi and a warning to include vitamines in the diet. The success of the oatmeal treatment of diabetes is ascribed to the presence of certain peculiar vitamines in that grain.

At the present time many of these ideas seem to most practitioners extremely fanciful and it is highly probable that increase in our information will prove at least some of them untenable. Nevertheless they will have served a good purpose if they have drawn attention to the fact that the construction of a diet is not merely a matter of protein, fat and carbohydrate including a desired number of calories. We are beginning to hear about the specific dynamic action of foods and will hear more. The whole matter of diet is in a more or less unsatisfactory state. The accepted methods of infant feeding change so rapidly that none but the active pediatrist is able to keep pace with them. The whole subject of feeding needs a deal of investigation and more than all, calm scientific judgment. Let us hope that it will get it in the not too distant future.

RECENT WORK ON BONE REGENERATION.

It is only three years since Macewen published his epoch-making monograph on the growth of bone, in which he announced the results of his experiments which apparently proved that periosteum is not a bone-producing tissue, but is simply a limiting membrane. This conclusion, which was directly at variance with the teachings of nearly two generations of histologists, has evoked considerable discussion, and there have been published along this line many investigations, some of which have confirmed while the rest have contradicted the observations of Macewen.

The latest report on this subject emanates from the Hunterian Laboratory of Experimental Surgery of Johns Hopkins University, and is contributed by J. S. Davis and J. A. Hunnicutt to the *Bulletin* of the Johns Hopkins Hospital, March, 1915. Many of Macewen's original experiments were repeated, and a number of new ones were performed, the animals experimented upon being dogs and rabbits. It was found that free periosteal transplants do not produce bone in the large majority of experiments, even though osteoblasts are adherent to the transplants; neither do pedunculated flaps of periosteum produce new bone. If, however, bone shavings are attached to these transplants, or flaps, new bone is produced in each experiment. One important fact demonstrated in these researches is that the removal of periosteum has little, if any, effect on the nutrition of a bone; the surface from which the periosteum is removed showing very little overgrowth of bone unless that surface has been greatly irritated.

Of eminent practical importance were the results of the investigations into the use of bone transplants in the repair of bone defects. Thus it was shown that auto- and iso-bone, without periosteum, is effective in repairing skull defects and in stimulating the growth of bone when transplanted into the periosteal tube after subperiosteal resection of

a rib. In the latter case the growth of bone from both the periosteum and the rib ends is stimulated. On the other hand, transplants covered with periosteum, and also foreign bodies, stimulate bone growth only from the rib ends. After subperiosteal resection of a portion of rib the repair of the defect takes place from the bone stumps, the periosteum acting as a limiting membrane. Whereas auto-bone, either with or without periosteum, lives and is successfully transplanted to fill defects in bone, clinically it is desirable to transplant bone covered, in part at least, with periosteum. Iso-bone in a bone defect acts as a scaffold for the growth of new bone from the living bone stumps, but in such cases there is always ultimate absorption of the transplant. When transplanted into soft parts both auto-bone and iso-bone are eventually absorbed.

THE LOCAL INCIDENCE OF CANCER IN RELATION TO FUEL.

THE local incidence of cancer is a very interesting study anywhere and withal of considerable value in tracing its cause. Mr. C. E. Green, writing in the *Edinburgh Medical Journal* for January, 1915, speculates upon the local incidence of cancer in France. He takes as his text statistics given out by the French Ministry of the Interior, and three diagrammatic maps given in an article in *La Presse Médicale*, May 13, 1913, by M. Bertillon, which show the deaths from cancer per 100,000 inhabitants living in different parts of France. The comparative death rate in town and country districts for the year 1908 is striking, the average per hundred thousand being in the towns 103 deaths and in the country 62.

M. Bertillon seeks in vain to find an explanation for this curious distribution. At first sight, the distribution seems to follow the geological map of France, the deadly square lying in the basin of which Paris is the center, but this, he admits, cannot apply to Pas de Calais, Nord, and Somme, which do not form part of the basin and yet suffer much from cancer. The map follows to some extent that of the alcoholic consumption but yet he points out that Brittany, which suffers little from cancer, has a large alcoholic consumption. On the contrary, Indre-et-Loire, Loire-et-Cher, and other districts very cancerous are not very alcoholic. He concludes that for the distribution there is certainly a cause and probably a unique one, but he has not yet discovered it.

Mr. Green thinks that the cause is connected with the nature of the fuel burned in the various departments, coupled with the fact that the further one goes north, the colder the country is in winter and the more fuel must necessarily be burned. From an analysis of the maps it is shown that where the cancer mortality is highest coal is burned, and Green comes to the conclusion, a conclusion strengthened by the result of his investigations in Orkney, that the composition of the coal has much to do with the causation of cancer. In districts of Orkney in which peat containing a very high sulphur percentage is burned, cancer is common. In those parts of France in which cancer is frequent, the coal burned contains a large percentage of sulphur.

Although the author is willing to admit that some other element than the strictly sulphur content may be involved in the relationship of certain fuels to the cancer death rate, yet he is of the opinion that the results of such enquiries as he has made into the fuel conditions of those districts where cancer is rife seem to point conclusively to the fact that the etiology of malignant disease has some subtle connection with fuel and the products of its combustion.

THE NECESSITY OF ANIMAL EXPERIMENTATION TO PROGRESS IN MEDICINE.

AT a stated meeting of the Pathological Society of Philadelphia, on March 11, a symposium was held dealing with "The Rôle of Experimentation in the Development of Modern Medicine." Dr. Joseph McFarland presented a communication entitled "Experimental Investigations of the Protozoa, Especially in Regard to African Lethargy." He pointed out how inadequate and circumscribed had been knowledge of two important diseases due to protozoa, namely malarial fever and sleeping sickness, prior to the application of the experimental method in their study, and the advance that had been made in this respect since the observations of Laveran, Ross, Golgi, and others bearing upon malaria and those of other investigators bearing upon trypanosomiasis. Only by means of animal experimentation had it been possible to demonstrate the respective causes of these two diseases, their modes of dissemination and reproduction, and to devise ways and means for their repression, prevention, and cure. As a measure of safety experimental observations must necessarily first be made on lower animals and their results may subsequently be confirmed by parallel observations on human beings.

Dr. Daniel J. McCarthy read a paper entitled "Experimentation in the Advance of the Study of Nervous and Mental Disease." He showed how our knowledge of the physiology of the nervous system was enhanced by experimental observations upon lower animals, without which much of a practical character as to the behavior of nerves, cerebral localization, cerebellar activity, mental processes, and the like, would be beyond ascertainment.

Dr. Lawrence F. Flick read a paper entitled "Experimentation as Illustrated in the Crusade Against Tuberculosis." He dwelt upon the fact that the transmissibility of tuberculosis as a disease had long been appreciated as an abstract principle, but the knowledge had been lost until it was possible to make a concrete demonstration by means of animal experimentation. It is only since Koch established the fact that the disease is due to the tubercle bacillus, from which it derives its transmissibility, that it has been practicable to employ intelligent measures for its prevention and cure. As a result there has been in the intervening time a noteworthy reduction in the incidence of the disease and in its mortality.

A NEW THEORY OF EPILEPSY.

Sir Arbuthnot Lane and his followers have laid at the door of intestinal stasis a formidable list of diseases and complaints. Although, perhaps, the majority of physicians and surgeons do not go so far as Lane in attributing to chronic constipation the many ills which he attributes to the condition yet all are agreed that chronic constipation, which generally means intestinal stasis, is responsible for many more or less grave affections. In the *Southern California Practitioner* for March, 1915, is a paper by Dr. Charles A. L. Reed of Cincinnati on the nature and care of epilepsy, the paper being an extract from an address on "Constipation in Relation to Various Diseases" delivered before the Los Angeles County Medical Association on Feb. 18, 1915.

Reed states that observation of facts occurring in his practice has taught him that constipation due to strictly mechanical causes exists in exactly one hundred per cent. of epileptics. In other words, every case that has come to him has been shown, first by clinical examination, next by *x*-ray findings, and finally, in all instances that have come to operation, by surgical exploration, to have some mechanical interference with the free activity of the bowels. Furthermore, the result of the experience is the fact that in certain cases the surgical relief of this anatomical condition is followed by corresponding relief of first the constipation and next the epilepsy. The third and probably the most important conclusion that has been forced upon Reed by his clinical observation is to the effect that the rôle of constipation as a causative factor in epilepsy is due to the more than likely fact that the initial cause of the disease is to be found in a specific infection.

The probable nature of this microorganism and its habitat are discussed and the assumed constitutional effects of the "Bacterium epilepticus" are dealt with. Emphasis is laid on the point that the bacterium becomes effective through increased absorption due to mechanical constipation, and that the cure of the constipation must be considered the first step in the logical cure of epilepsy. Consequently operation is recommended to remove the constipation, and this removal invariably affords relief to and sometimes cures the epilepsy.

Cure of Masked Syphilis after Wassermann Diagnosis.

In theory it should constantly occur, and in practice we know that it is not uncommon for people to recover their health rapidly from conditions in no wise resembling syphilis but in which the patients give a positive Wassermann reaction. In literature, however, we do not find many separate articles on the subject, so that each one reported carries with it an important message to the practitioner. In a paper on this subject read last Fall by von Bergmann before the Altona Medical Society (*Muenchener medizinische Wochenschrift*, January 26), a number of such cases were reported in which the treatment was restricted to large doses of potassium iodide. In the Altona Hospital, with large venereal service, the Wassermann test is used as a matter of routine, as are albumin and sugar tests of the urine. With the test positive the iodine tolerance is determined, and when it is normal large doses of potassium iodide are pushed. Two of the more remarkable cases appeared to suffer solely from scrofulous or tuberculous suppurating cervical glands which had been treated in vain by the seemingly indicated methods. These made good recoveries. In other cases syphilis must have been suspected but had not responded to treatment.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—*Contributions* for the week ending May 1, 1915:

Dr. N. D. Murphy, Bangor, Mich.	$25.00
Col. W. H. Arthur, M. C., U. S. A., San Francisco, Cal.	10.00
Dr. Augustus A. Eshner, Philadelphia, Pa.	10.00
Dr. S. W. Goddard, Brocton, Mass.	10.00
Dr. Albert M. Judd, Brooklyn, N. Y.	5.00
Dr. Calvin F. Barber, Brooklyn, N. Y.	10.00
The Mount Vernon Medical Society, Mount Vernon, N. Y.	10.00
Receipts for the week ending May 1st.	$80.00
Previously reported receipts.	6,505.50
Total receipts	$6,585.50
Disbursements for the week ending May 1:	
35 Standard boxes of food at $2.30. $80.50	
Previously reported disbursements:	
1,625 Standard boxes of food at $2.20 . . . $3,575.00	
1,274 Standard boxes of food at $2.30 . . . 2,930.20	
Total disbursements	6,585.70
Deficit	$0.20

F. F. Simpson, M. D., Treasurer,
7048 Jenkins Arcade Bldg.,
Pittsburgh, Pa.

Audit of the Treasurer's Account.—In a letter dated March 26, addressed to the Chairman of the Committee, Messrs. Marwick, Mitchell, Peat & Company state: "We have audited the accounts of the 'Committee of American Physicians for the Aid of the Belgian Profession' for the quarter ended March 20, 1915. We hereby certify that all donations received have been properly accounted for and applied to the purchase of provisions and that the following is a correct summary of the receipts and disbursements for the period:

Receipts	$5,221.50
Disbursements.	
1,625 boxes of food.	3,575.00
Balance on deposit in Union Trust Company, Pittsburgh, Pa.	$1,646.50

"All but nine of the boxes of food had been delivered at the Bush Terminal, South Brooklyn, New York, to 'The Commission for Relief in Belgium' as at the date of our audit, and in addition 715 boxes have been ordered, bringing the total of the boxes up to 2,340. The foregoing bank balance will be used to pay for the 715 boxes on order."

The Situation in Belgium.—Dr. J. Riddle Goffe, of New York writes that in a letter just received from Dr. Jacobs, of Brussels, he summarizes the situation of our Belgian colleagues as follows: (1) Many doctors were killed, consequently the widows and orphans deprived of everything, are without a home, without means, with nothing left. (2) All country doctors or those living in small towns are ruined by loss of every possession they had. (3) Doctors in large cities are ruined by commandeering, war-levies, etc. (4) The largest part of Belgium's population has become the prey of infectious diseases, epidemics, with a large infant mortality, etc. (5) Ruined civilian populations cannot pay for medical advice, consequently many physicians

are compelled to work for nothing, others are obliged to undertake any labor for gain as a means of livelihood. The opportunity is here created for the medical profession of the world to show the brotherly feeling which exists among them, and they can do this by helping us with the necessary funds.

More Red Cross Surgeons and Nurses for Europe.—Five Red Cross surgeons and eighteen nurses sailed from New York last Saturday. One surgeon and eight nurses are going to Austria-Hungary, four nurses to Germany, two surgeons and five nurses to Serbia, and two surgeons and one nurse to England. The two surgeons going to Serbia will take the places of Drs. Donnelly and Magruder, who died recently of typhus. The others in the party will take the places of Red Cross workers whose terms of duty have expired. Drs. Shadworth O. Beasley of San Francisco and W. A. Jolley of Boulder, Col., go to Serbia; Dr. Walpole Brewer of Tuskegee, Ala., goes to Vienna, and Dr. Dunlop P. Penhollow and Herbert H. Howard of Boston go to England.

Red Cross Donations.—Between September 12, 1914 and April 17, 1915, the American Red Cross sent to Europe more than 1,200 bales of an average weight of 500 pounds each of absorbent cotton; surgical gauze that if stretched in a single line would reach from the Battery, in New York, to Niagara Falls; more than 32,600 pounds of chloroform and ether; over 65,000 yards of bandages, and 1,123 cases of surgical instruments. To Germany have been forwarded 85,000 pounds of medicated cotton, 10,300 yards of bandages, 122,000 yards of plain and surgical gauze, 4 automobile ambulances, 66 cases of surgical supplies, 5,500 pounds of chloroform and ether, and large quantities of miscellaneous supplies such as antitoxins, rubber goods, hospital clothing, etc. To Austria-Hungary have been shipped 67,600 pounds of cotton, 113,000 yards of gauze, 4 automobile ambulances, 5,000 pounds of chloroform and ether, in addition to large shipments of surgical crinoline, drugs, surgical instruments, hospital clothing, and other Red Cross supplies. Similar gifts have been sent to relieve the sufferings of English, French, Russian, and Serbian soldiers.

Synthetic Food.—The German chemists are devoting their energies to the production of food materials to take the place of those the enemy will not let them have. We noted recently the statement that they proposed to make bread from straw and now it is announced that a process has been invented at the Institute for Fermentation Industry at Berlin whereby albumin can be made from sugar and ammonium sulphate.

Colonel L. Mervin Maus, Medical Corps, U.S.A., retires today, having reached the age limit of 64 years. He was the senior of the Medical Corps in respect to length of service, having been commissioned over forty years ago.

Dr. G. B. Young, the very efficient Health Commissioner of Chicago, retired on May 1, his term of appointment having expired, and has resumed his duties as surgeon in the U. S. Public Health Service.

Professor C.-E. A. Winslow, formerly assistant professor of biology at the College of the City of New York and curator of public health at the American Museum of Natural History in this city, has been appointed to the Anna M. L. Lauder professorship of public health in the Medical Department of Yale University.

Dr. Leo J. Dretzka of Milwaukee has been appointed superintendent of the new Detroit City Hospital.

Dr. A. Szwajkart has been appointed director of the Cook County Psychopathic Hospital to succeed Dr. H. L. Davis who retires after ten years of service.

Dr. J. Chalmers Da Costa was the guest of honor at the annual banquet of the Northern Medical Association of Philadelphia on April 27. Addresses were made by Drs. James Tyson and Wm. M. Walsh, and Dr. Thomas R. Shriner acted as toastmaster.

Dr. Hardman N. Kinnear of the American Board's Hospital at Foochow, China, has received the decoration of the Sixth Order of Chia Ho from President Yuan in recognition of valuable services in connection with relief work during the revolution. He has also been made a life member of the Red Cross Society of China.

New York City Death Rate.—During the week ending April 24 there were in this city 1,748 deaths, giving a death rate of 15.71 per thousand of the population, as compared with 1,637 deaths and a rate of 15.30 for the corresponding week of 1914, a decrease in the absolute figures of 11 deaths and in the relative figures of 63 deaths.

Coming Society Meetings. — THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION will meet at the Hotel Chamberlain, Old Point Comfort, on May 11-14, under the presidency of Dr. Samuel E. Smith of Richmond, Ind. The secretary is Dr. Charles G. Wagner of Binghamton, N. Y.

THE ASSOCIATION OF AMERICAN PHYSICIANS will hold its thirtieth annual meeting in the Raleigh Hotel, Washington, on May 11-13, 1915, under the presidency of Dr. S. J. Meltzer of New York. The program contains the titles of seventy-three papers.

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS will hold its second annual meeting at the New Willard Hotel, Washington, on May 10, 1915, under the presidency of Dr. Gerald B. Webb of Colorado Springs. The secretary is Dr. Martin J. Synnott of Montclair, N. J.

THE AMERICAN PEDIATRIC SOCIETY will meet at the Laurel House, Lakewood, N. J., on May 24-26, under the presidency of Dr. George N. Acker of Washington, D. C. The secretary is Dr. Samuel S. Adams, 1801 Connecticut Avenue, Washington, D. C.

The Mayo Foundation Rejected.—The Minnesota Senate on April 30 passed a resolution providing that "the University of Minnesota shall not affiliate with or delegate its teaching functions to any person, firm, or corporation not under the exclusive supervision and control of the board of regents." This was aimed at the Mayo foundation which it was planned to affiliate with the medical department of the Minnesota State University. The plan had already met with considerable opposition by the physicians of the State, especially in St. Paul and Minneapolis.

Pay for Birth and Death Certificates.—Governor Whitman has signed the Seely bill, which provides that municipalities shall pay physicians 25 cents for each birth certificate or death certificate properly made out and filed. It is estimated that the new law will cost New York City about $50,000 a year. An example of the inconvenience, to use no stronger word, which may be caused by the all too common neglect to file death certificates is given in the Weekly Bulletin of the Department of Health. "Three or four months ago a young man, Francis W., born in the borough of Brooklyn on September 23, 1898, after constant attendance at the movies,

worked his way to England and enlisted in the English Army. A month's stay in a training camp so robbed war of its glamour that he wrote to his mother to send him over his certificate of birth. A careful search of the Health Department's records showed that no certificate had been filed at the time of Francis' birth, an omission which will compel the young man to go to war and make himself a target for German bullets."

Tuberculosis Hospital Admission Bureau.—The New York City Health Department calls attention of physicians to the fact that tuberculous patients should not be referred to any special hospital directly but should first be sent to the Tuberculosis Hospital Admission Bureau, 426 First Avenue, for examination and admission in due form. The Bureau receives applications for and admits to the following tuberculosis institutions: Hospitals—Bellevue; Brooklyn Home; Metropolitan; Montefiore Home; New York Throat, Nose and Lung; Riverside; St. Anthony's; St. Joseph's; St. Vincent's; Sea View, and Seton. Sanatoria—Municipal Sanatorium, Otisville, N. Y.; New York State Hospital for Incipient Tuberculosis, Ray Brook, N. Y.; Montefiore Home Country Sanatorium, Bedford Hills, N. Y. Preventoria—Tuberculosis Preventorium, Farmingdale, N. J.; Tuberculosis Preventorium, Nanuet, N. Y.

Resident Physician Wanted.—The Philadelphia Civil Service Commission will hold a competitive examination on June 2 for the position of resident physician in the Department of Public Health and Charities. Salary $600—$900. Contestants must be American citizens and residents of Philadelphia. Detailed information may be obtained from the office of the Commissioner, Room 875 City Hall, Philadelphia.

The Late Dr. Charles E. Lack.—The following minute has been sent for publication: "We, the members of the Norwegian Hospital Alumni Association, wish to record our deep sorrow in the death of our beloved friend and fellow worker, Charles Eugene Lack, M.D. Those who have been associated with him in the medical calling for many years can best appraise those fine qualities of mind and heart which marked him above men. As a physician he was gifted and industrious, conscientious and self-sacrificing. As a friend he was of sterling character and lovable disposition. The loss of his activity and comradeship will continue to be felt by all the members of this society. To his sorrowing relatives we venture to offer this expression of our deep-felt sympathy in the great bereavement that has come to them, asking them to find comfort in the circumstance that their loss is shared by an innumerable company to whom Dr. Lack was most dear, alike as physician and friend. Therefore, be it resolved that this notice be entered upon a separate page of the minutes of this society and that a suitable copy of this memorial be forwarded to the family of the deceased and to the medical press of this city.

"Reflect that life, like every blessing,
Derives its value from its use alone."

W. Carl Schoenijahn, M.D., Robert Emmet Coughlin, M.D., *Committee on Resolution.*

The Late Dr. John Patrick McGowan.—The Medical Board of the N. Y. Foundling Hospital at its regular monthly meeting held April 1, 1915, passed the following resolutions: *Whereas*, death has called from us our colleague and fellow member, Dr. John Patrick McGowan, and *Whereas*, by his demise the Sisters of this Institution have lost a devoted friend, the Medical Board a loyal member, and the little children to whose relief and comfort he administered for so many years, a resourceful and skillful physician,

Then be it resolved, that the Medical Board, through its secretary, offer its condolence and express its sense of loss to the bereaved widow and family, and further

Be it resolved, that these resolutions be spread upon the minutes of this board, and a copy be sent to the widow of the deceased and to the medical journals for publication.

(Signed) JOHN J. REID, M.D.,
JOSEPH KENEFICK, M.D.,
Committee.

Obituary Notes.—Dr. JAMES W. BROWN of Grass Valley, Cal., a graduate of the Northwestern University Medical School, Chicago, in 1877, died at his home, after a short illness, on April 5.

Dr. GEORGE VEITCH of Port Elgin, Ont., a graduate of Trinity Medical College, Toronto, in 1885, died at his home, after a long illness, on March 18, aged 55 years.

Dr. WILLIAM BRITTON of Toronto, Ont., a graduate of the University of Toronto, Faculty of Medicine, in 1875, died on March 11, after a long illness.

Dr. EDWIN CROCKER of Narrowsburg, N. Y., a graduate of the Albany, N. Y., Medical College, in 1868, and a member of the New York State and Sullivan County Medical Societies, died at his home on March 26, aged 75 years.

Dr. JOHN ALSDORF of New York, a graduate of the College of Physicians and Surgeons, New York, in 1880, died at his home on March 25, aged 72 years.

Dr. T. T. TATE died at Gettysburg, Pa., on March 20, at the age of 84 years. He was graduated from the Pennsylvania Medical College of Gettysburg in 1855. He served as Lieutenant and Surgeon of the Third and Seventeenth Pennsylvania Cavalry during the Civil War.

Dr. MICHAEL C. DRENNAN died at Easton, Pa., on March 23, at the age of 77 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863. For meritorious services as surgeon in the United States Navy during the Civil War he was retired in 1899 with the title of Rear Admiral.

Dr. DANIEL JOSEPH O'SHEA of Boston, Mass., died at his home from pneumonia, after a short illness, on March 22, aged 39 years.

Dr. JAMES E. MCGOURTY of New York, formerly of Worcester, Mass., a graduate of the Harvard University Medical School, Boston, in 1896, and for some years surgeon in the Ninth Massachusetts regiment, died at the Flower Hospital, New York, from pneumonia, after a short illness, on March 28.

Dr. AUSTIN W. ALVORD of Battle Creek, Mich., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1868, a veteran of the Civil War, and a member of the Michigan State and Calhoun County Medical Societies, died at his winter home in St. Petersburg, Fla., on March 23, aged 78 years.

Dr. WILLIAM JULIUS PASMORE of Deseronto, Ont., a graduate of the Toronto School of Medicine in 1866, died at the Wellesley Hospital, Toronto, from angina pectoris, on March 18, aged 73 years.

Dr. WILLIAM R. STAVELY died at Lahaska, Pa., on March 31 at the age of 83 years. He was graduated from Jefferson Medical College in the class of 1855.

Correspondence.

MEDICAL EXPERT TESTIMONY.

To the Editor of the Medical Record:

Sir:—I enclose a letter from Judge A. T. Clearwater of Kingston, president of the New York State Bar Association, which I submit to you for publication together with an amendment to the Judiciary Law, which is a long step in the direction of doing away with some of the objectionable features of medical expert testimony. Having for years worked with this distinguished jurist as a member of the committee on Expert Medical Testimony I am deeply mindful of the obligation the profession is under for his faithful and disinterested labors.

John A. Wyeth, M.D.

April 24, 1915.

My Dear Dr. Wyeth:

I enclose for your information a bill relative to medical experts, which, as you doubtless know, was strongly advocated by me as president of the New York State Bar Association, and chairman of its committee upon medical expert testimony which passed the Legislature and has just been approved by the Governor.

The bill is not all that I would like it, but it accomplishes much that we have been struggling for for many years in that it provides for the appointment by the court of three disinterested competent physicians, whose compensation does not to the slightest extent depend upon the party calling them, and provides that they shall be paid from the public funds such sum as the judge appointing them may determine to be just and equitable. Will you kindly advise your associates of the passage of the bill which in the multifarious legislation of the session has escaped public attention.

I trust that to some extent at least it will serve to eliminate some of the so-called experts whose appearance has been a disgrace alike to the administration of justice and to the profession which they misrepresent. Permit me to extend to you my congratulations upon this becoming a law.

With many kind regards, I am, as ever,

Very sincerely yours,

A. T. Clearwater.

An Act to amend the judiciary law in relation to the appointment of examining physicians in criminal or special proceedings.

The people of the State of New York, represented in Senate and Assembly, do enact as follows: Section 1. Chapter 35 of the laws of 1909, entitled "An act in relation to the administration of justice, constituting chapter 30 of the consolidated laws," is hereby amended by inserting therein a new section after section 30 thereof, to be section 31, to read as follows:

Section 31. Examining physicians.—In a criminal action or proceeding or in a special proceeding instituted by the State writ of habeas corpus or certiorari to inquire into the cause of detention, in which the soundness of mind of a person is in issue, the court in which or the judge or justice before whom the action or special proceeding is pending may appoint not more than three disinterested competent physicians to examine such person as to his soundness of mind at the time of the examination. Any such examining physician may be sworn as a witness at the instance of any party to the action or proceeding. The compensation of such examining physician for making such examination and testifying, when certified by the presiding judge or justice of the court or judge or justice making the appointment, shall be paid out of any funds available for the payment of and in the same manner as other court expenses.

This act shall take effect immediately.

Blood Findings in Rubella. — H. Saito states that there is a slight diminution in the hemoglobin content as the eruption fades. There is an increase in the neutrophiles and a leucopema at the height of the eruption. Eosinophilia is frequent, especially when the eruption is fading.—*Zeitschrift für Kinderheilkunde.*

OUR LONDON LETTER

(From Our Regular Correspondent.)

METRIC SYSTEM—PATENTS IN REFERENCE TO REMEDIES—WOUND INFECTIONS IN WAR—OBITUARY.

London, April 25, 1915.

The advocates of the metric system do not seem to make much progress with prescribers. Not for want of energy, for some of them push it in season and out. We have to get familiar with it in relation to chemistry, but we seem to hold out against it in pharmacy. Perhaps because its use involves so much revision of our ideas of dosage. There is something in halves, quarters, eighths, and so on which we do not want to miss or exchange for divisions to which we are less accustomed. When an enthusiast assures me the system is certainly coming, I am content to admit the fact, adding that its pace is rather slow—like that of many other reforms. I have heard the same prophecy for so many years that I feel I may safely go on in the old way, for its arrival will hardly be celebrated in this generation though its adoption by the pharmacopœia may have quickened its pace.

Applications have been made to the Comptroller-General of Patents to void or suspend various German patents under the legislation passed since the war began. Among these applications are some relating to so-called patent medicines, and they illustrate once more the way in which certain products are imposed on the public by advertisements without authority beyond the assertion of the person who makes himself a proprietor by labeling a drug with a fancy name. Thus a definite chemical compound was sent over here under its trade name, well advertised under that name, and even prescribed under it by some either ignorant of its nature or thoughtless enough to accept it as a new remedy on the authority of the exporter's say-so. Now application is made for permission to sell the drug, which is made here, under the name of the product which has been extensively imported from Germany. So you see English firms instead of competing in scientific manufactures are content to become mere vendors of the advertised goods they might be expected to produce. This case was adjourned as were some others of the kind. In another the comptroller ruled that without strong evidence that the interests of the public demanded it the court could not recommend the Board of Trade to transfer trade names, as it would be appropriating the good will of firms which had registered trademarks, and though we might wish to supplant the Germans no civilized country has yet gone so far as to take bank balances, and a good will was something of the kind. There then you have the way to get a good bank-balance—take a common, cheap drug, costing, say a penny, fix on it a fancy name, divide it into a thousand packets, and advertise them as a new cure-all at a shilling each, on which the government stamp promotes the sale as looking like a guarantee to the ignorant purchaser.

The war has naturally increased interest in wounds and everything relating to them. Sir A. E. Wright, who has been appointed consulting physician to the expeditionary force, gave an address on various factors and problems concerning wound infections at the Royal Society of Medicine's meeting of the 30th inst. Remarking that in this war every soldier's clothes and skin becomes contaminated with all sorts of filth containing pathogenic

organisms he said the projectile takes them with it and implants them far beyond the reach of prophylactic or any measures, making a track infected with streptococcus and fecal microbes. Two are of special import: gas-phlegmon bacillus and tetanus bacillus. The former, known also as the *Bacillus aerogenes capsulatus* of Welch, is a large gram-staining anaerobic, gas-forming microbe, found both in infiltrated superficial wounds and in deep ones. It freely discharges the frothy matter common in such wounds. The tetanus bacillus and its discharges are less abundant. The period during which these organisms are imprisoned is a critical one and makes the first stage of wound infection, during which the streptococcus or the *Bacillus tetani* may increase and produce its evil effects. As soon as there is a free outlet and the aerobic condition reestablished in the wound the bacterial flora changes. Instead of an infection of imprisoned discharges or of the tissues, there is infection of the granulating surface of the wound and the flowing discharges. This may subside and healing occur; or of the mixed organisms the streptococcus may continue with open chronic wound and discharging sinus; or again obstructed outflow may lead to suppuration and septicemia. Passing on to treatment Sir A. E. Wright said our ideal is healing by first intention—no interference by bacteria; but we are far from attaining it. Yet three therapeutic measures are at our disposal: (1) antiseptics, (2) physiological methods such as opening and draining the wound, which will bring the antibacterial powers of the blood to bear on the microbes, (3) reinforcement of these powers by vaccine therapy, etc. Of these the second he declared beyond all question the most important, notwithstanding loud talk about antiseptic treatment, which is only ancillary as is also that by vaccine and similar methods.

Another fundamental consideration is that we cannot apply physiological treatment to the greatest advantage without full understanding of the processes going on in the wounds, and we do not yet understand them even in outline. Our task then is to discover what goes on in the wound and follow out its biological evolution. Towards the accomplishment of this Sir A. E. Wright formulated and commented upon the following questions:

I. Can the microbes which are found in wound infections live and multiply in the unaltered blood fluids?

II. Does the lymph which pours into the wound provide a favorable nutrient medium for the microbes which have been growing in that wound?

III. What is the cause of that "corruption of the lymph" which converts it into a favorable nutrient medium for sero-saprophytic microbes?

Surgeon-General Sir Gerald Bomford, late Director-General, Indian Medical Service, has died at the age of 63. He entered the army in 1874, was in the Perak expedition 1875-6, for which he was awarded medal and clasp in the military department. He was appointed professor at the medical college, Calcutta, where he had been surgeon, and became acting principal in 1893. He had been secretary to the Calcutta Sanitary Commission from 1888-90. He qualified at the Royal College of Surgeons in 1873 and took the medical degree in London the next year. He was created K. C. I. C. in 1909.

Dr. William Arthur Brailey, consulting surgeon to Guy's Hospital, has died at the age of 69. He was Hunterian professor at the Royal College of Surgeons in 1885-6 and has made many contributions to ophthalmology.

Dr. W. T. Edwards of Cardiff, who was the senior medical man in Wales, has died at the age of 93. He was J. P. for the county, and served many years in the various honorary local positions, among them president of Cardiff Infirmary and consulting physician to Glamorgan and Monmouth Infirmary and a seamen's hospital ship. He graduated at the London University in 1850, having been a member of the Royal College of Surgeons from 1842 to the fellowship of which he was elected in 1879. At the Cardiff meeting of the British Medical Society he was president.

Bernard Roth, F.R.C.S., whose position as a leader in orthopedy is well known on your side as well as here, has died. His father was an orthopedic surgeon and he leaves a son who follows in the same line, but who is just now serving at the front. He had retired for some years and spent much of his time at Brighton, where he was made a J. P. He had also magisterial duties in Middlesex and was a visiting justice to prisons.

A RED CROSS SURGEON IN SERBIA.

[Extracts from the diary of Dr. James F. Donnelly, of New York, who died of typhus fever in Serbia last February.]

GHEVGHELI, SERBIA, December 18: Arrived here at noon and visited a silk factory that has been turned into a hospital, with 2000 patients. Such a sight of suffering that it makes one's heart bleed. I hope to be able to make the best of things and do something to help.

December 19: I have done my first operation here, and extracted a bullet from the neck of a Serbian soldier, and to-day have dressed the wounds of about 100 patients. The conditions are terrible.

December 20: This little town in the southern part of Serbia has a beautiful climate and we are not exposed to any danger, as the fighting goes on about 500 miles north, and the wounded are sent here by rail. The suffering of these poor people is piteous and their endurance marvelous; they let one operate and not an outcry!

December 21: We had five operations to-day and took off the legs of three soldiers with gangrene of the feet. To make a round of the hospital, with its sounds, its odors, and its suffering is a terrible experience. I have just been ordered by Dr. Butler to make the rounds of all patients and have them ready in the morning for operation, so expect to-morrow will be a busy day. I have a small room with two other doctors, with no comforts whatever and many rats, and I feel some vermin on me. Sherman spoke the truth when he said war was hell. I never want my little son to be a soldier.

December 23: We are very busy here with 2000 patients, and the horror of it makes my heart sick and cures me of wanting to talk about the war. We get little news here, only the French papers from Greece.

Christmas Eve: Another big day. It is 8 P.M. and I have just come back to my room and am writing this by candlelight. I will get to bed by 8:30, as I am dog tired and need the rest. The bed is hard and has not been made up since we got here.

Christmas Morning: My first thoughts this morning flew to my wife and little son. I hope from the bottom of my heart they will have a Merry Christmas. I wish I were nearer to them. It is half-past

seven, and after a cup of tea and a slice of black bread we are to make the rounds and operate on twenty patients, and that will be our Christmas Day.

Christmas Evening: Was in the hospital all day until 6 P.M. For dinner we had a roast pig three weeks old, fruit, candy, and some red wine sent us from Salonica.

December 31: The last day of the year, and what a year! Spent the whole day in the hospital, trying to relieve the suffering,—that is the best way I know to wind it up.

January 4: We are at last getting things into some shape. At the start, with all the suffering, we could get little food or milk; now things are looking better, and in another month we hope to have them in good shape.

January 5: Received orders to-day to move to our new quarters, opposite the hospital. If we can get a few necessaries together I believe we shall be more comfortable. We have not had many comforts as yet. I am writing this by the light of a lamp, which is better than the candle.

January 6: This is the day before Christmas for the Serbians and this morning four little children came to our floor and sang Serbian national songs. We gave them each ten cents and they went away happy. The view from our window here is beautiful, we can see the snow mountains about 5 miles away. To-day I worked on the grounds with Austrian prisoners, digging holes for waste. It is like a spring day, much too warm for an overcoat, and with little wild flowers growing everywhere. The hospital has just received 100 pigs, so patients and soldiers will have pig for their Christmas dinner. They need a good meal, poor things.

January 12: This afternoon I went about 5 miles from town for a few barrels of water. Five miles in a heavy rain, on a poor road, in a cart with two Austrian prisoners who could speak neither English nor German. I took a hot sulphur bath at an old Turkish bath, very primitive, and have just come back in a broken down carriage, leaving the two soldiers and the driver to get back the way they came. I am writing this in a little Turkish café and have ordered hot tea with lemon and sugar, to ward off a chill. A Turkish boy has sold me two hard-boiled eggs for 5 cents, so this is my supper.

January 13: I am writing on the second floor of a barn, which we have turned into a surgical ward. To-day I have gone back to my usual work of dressing patients. Yesterday was a bad day and I must be pretty tough to stand it, in the wet all day long. But I don't grumble, for I brought in a ton of pure water from the mountains, and had a new experience. To-morrow is the Serbian New Year. Everything is very quiet; no one comes through except the soldiers on the way to the front. It is sad to see them—young men for the most part; no overcoats, carrying only a gun, cartridges, and a big loaf of bread.

January 18: Have been working in the operating room all day. We are getting some typhus and typhoid cases, but cannot do much for them. Our death rate is about six a day, which is fair considering that we have 2000 patients.

January 19: A relative of the King's came to the hospital. She was very charming, and questioned us about ourselves. Only two of the six doctors were married. When I told her I had a little boy she said, "If your wife and boy come to Serbia be sure to let me know and you must be presented to the King." Have just seen an English paper of January 12, and it looks as if Italy and Roumania would come into the fight. They might as well come in and get it over with. It is now nearly 9 P.M. and we are about ready to get to bed. We get up at 6 o'clock, breakfast on bread and tea at 7, and by 7.30 are in the hospital making the rounds and operating. It has been raining hard for twenty-four hours; we can't complain of the weather; at Nish and Belgrade they have had some heavy snows, but we have had none here yet and it looks like a mild winter. They seem to be gathering their forces to strike a heavy blow by springtime. I am not anxious to see any more suffering.

January 24: Am to be on duty in the pest house for a few days, in charge of a doctor who has typhus fever.

January 25: I am writing in the pest house about two miles from town. It was built for cholera patients, but so far we have not had any, so smallpox, diphtheria, typhus, and all the infectious cases are sent here. Dr. Gouthes who went with me three weeks ago to the sulphur baths, is here with typhus. He was married last August and sent here by the Bohemia Red Cross. His wife is a nurse and has joined him.

January 26: Dr. Gouthes is much better, and has a good chance to get well and go North in a few weeks. A year or two ago there were about three hundred Serbian doctors; now there are only about seventy they say, and of this number half are ill and will never practise again. This is the result of war and hardships in the past four years.

January 27: I am alone in the building which has been turned into a laboratory, and am now assigned to examine all well water and look after the sanitary conditions generally, and it certainly is some job. Dr. Butler has gone to Nish.

January 29: To-day we had a visit from the Crown Prince George. He has been shot twice and is on his way to Italy to regain his health. He is single, about thirty years of age, and seems a good fellow. He gave some gold pieces to the patients in the wards.

January 30: It was an awful sight to see two hundred sick and wounded soldiers come into town to-day. Many fell by the roadside while trying to reach the hospital; some were without shoes. We did all we could for them and they are wonders and never complain. Human life here does not amount to much. The chap who makes the coffins takes great pride in keeping the boxes out in front of his shop, and the soldiers count them as they pass. An over-sympathetic individual in this part of the world could not last long.

February 7: To-day is Sunday and I am on duty all day looking after five hundred patients.

February 9: Rumors to-day that Bulgaria may enter the war and would strike this town first; we have all arranged to gather in our hospital and hoist the stars and stripes. Some prominent English surgeons passed through town to-day and I gather there will be plenty of work for all the doctors and nurses inside of a month.

February 13: I am at the station awaiting the arrival of Sir Thomas Lipton. His yacht *Erin* brought him to Salonica, with six doctors, twelve nurses, six orderlies, and three motor cars. He is on his way now to Nish.

February 14: It certainly was a great pleasure to have Sir Thomas Lipton as a guest for one hour yesterday. He remembered that we had met at the Lotus Club; he presented me to all his party—

about thirty in all—and we walked to the hospital together. It was a great sight to see how every one looked up to him, and how good and kind he was to all our doctors and nurses. He gave me a gold four-leaf shamrock which I shall keep for my wife. He also gave me his picture and is going to send me an American flag and an Irish flag. In about seven days he expects to pass through again on his way back to Salonica, and will write me when to expect him, so that I can be at the station to receive some tea and supplies which he wishes to present to our party.

February 17: When I see the suffering here my heart cries out. It is terrible to see young men dying like flies. There is no more wood to make the boxes and in the shed where the bodies are kept there are about forty awaiting burial. Dr. Gouthes is up and round again, but his wife is down with typhus.

February 18: I am at the station awaiting the arrival of Sir Thomas Lipton from Nish. I wish to thank him for the large American flag and the Red Cross flag he sent me. Later: He did not come, but is expected in a few days.

[Two days later Dr. Donnelly came down with typhus, and four days later he was dead, and was buried in the American flag that had been given him by Sir Thomas Lipton.]

"The first hospital I visited on my way to Nish," wrote Sir Thomas, "was at Ghevgheli. It was an American hospital and I was taken through every ward by Dr. Donnelly. There were some 1,400 patients, principally typhus. Many patients were lying without blankets or mattresses, just in their ordinary clothes. The condition of those patients was something terrible. I also saw some of the American nurses, out of twelve, seven of them lying sick of typhus and three of their doctors out of six down with the same thing. Dr. Donnelly came to the station to see me off, as fine a type of healthy man as you could see and of a happy, cheerful disposition. On my way back, when I got to the station at Ghevgheli, I looked for Donnelly, but to my great sorrow I learned that he had died the day before."

2. Pulse and Temperature in Leprosy.—J. A. Honeij has already called attention to the possible prognostic value of the morning increase in pulse rate. The present detailed clinical study covers a period of twelve months from July 14, 1913, to July 14, 1914. In all, seventeen patients have been under observation for various periods during two years, and fourteen patients have been under constant observation for eighteen months. The study of the temperature and pulse has given definite results and the following points are now presented: There occurs a definite clinical temperature and pulse curve diagnostic and prognostic of leprosy. There is a frequent and persistent occurrence of a high morning pulse rate—"morning pulse"—in all cases. A constant high pulse rate is most marked in progressive and advanced cases. A persistent high pulse rate without a corresponding elevation of temperature of prolonged duration is found after "toxic-febrile" attacks. There is a correlation of temperature and pulse in early cases, in contrast to a gradual increase of pulse rate without similar temperature reactions in progressive and advanced cases. Not uncommonly a low evening temperature is present. A marked irregularity in temperature and pulse exists during complications not associated with leprosy. There are typical "toxic-febrile" temperature and pulse curve reactions. Marked temperature and pulse reactions occur from otherwise insignificant causes, both physical and mental.

3. Skeletal Cancer.—E. H. Risley points out the following facts of importance in regard to metastatic bone cancer: Metastasis takes place probably by centrifugal spread along the lymphatic plexus of the deep fascia in most cases. Bone metastases occur almost entirely in the areas of the body subject also to skin nodule metastases, *i.e.*, everywhere proximal to the elbow and knee joints. Bones distal to these joints are very rarely involved. Metastases are more common after cancer of the breast than any other organ. The prostate and thyroid being the next most common. (Hypernephroma of the kidney is not considered in this series.) The liability of a bone to cancerous invasion increases with its proximity to the site of the primary focus. Thus the sternum and ribs are affected about equally and more frequently than any other bones. The spine, femur, humerus, pelvic and cranial bones come next. The character of the secondary lesion always corresponds to that of the primary growth. The frequency after cancer of the prostate may be as high as 25 per cent. The vertebrae are the favorite seats of attack in scirrhus of the breast. The percentage of vertebral metastases is nearly 25 per cent. Spontaneous fracture is present in about 24 per cent. Pain is the only characteristic symptom. Visible or palpable tumor is rare, while spontaneous fracture is quite common. One may set down the following points as diagnostic aids: Any fracture of a long bone occurring as a result of trivial injury should immediately suggest the possibility of bone metastases and lead to careful search for the primary new growth. In all cases of painful paraplegia a neoplasm should be suspected. A diagnosis of primary bone tumors should never be made without very careful examination of the abdomen, mammary glands, prostate, and thyroid for malignancy. It is rare that careful search will fail to reveal the primary focus.

5. The Tobacco Heart.—Harlow Brooks states that tobacco produces symptoms referable to the heart, of a very definite and characteristic type. These are first manifested by an increase in rate, with a rise of blood pressure, later by a slowing with a fall in pressure. These symptoms are apparently due to vagus effects, and quickly disappear when the drug action passes. These symptoms all diminish in degree with habituation to the drug, though they may be probably aroused in

almost any instance by increasing the dose and in many cases by changing the form of administration. Prolonged excessive administration of tobacco induces arrhythmia and intermission. These symptoms are more or less persistently accompanied by a sense of weight or of pain of a dull persistent character in the heart region. Pain may be entirely independent of alterations in rhythm, though most likely to occur with a slowing of the usual rate. So far as can be surmised from experimental evidence and from clinical observation, these symptoms are not due to vagus disturbance, but to claudication of the coronary vessels. They are more likely to appear in chronic smokers than in beginners, and in long standing rather than in recent tobacco habituation. Tobacco angina pectoris is in all symptomatic respects similar to the true angina pectoris caused by coronary disease. It occurs with considerable frequency in chronic tobacco poisoning. It is unusual if not unknown in acute tobacco poisoning, and long habituation to the drug predisposes to this symptom. It is relieved by the usual vasodilators and also by morphine. It is commonly succeeded or preceded by a sense of pain in the precordium. The angina of tobacco poisoning is entirely relieved and commonly does not recur if tobacco is given up. In many instances one attack appears to sensitize to others. This sensitization seems to disappear very slowly. So far as can be determined, this symptom is due to a coronary claudication, and it is entirely or almost free from vagus effect. There is no clinical nor experimental evidence that disease of the heart muscle is caused by tobacco, save for possible changes in the papillary muscles, probably explainable on a mechanical basis. The fact that all symptoms disappear when tobacco is discontinued seems to confirm this statement. There is neither clinical nor anatomical evidence sufficient to indicate that true coronary sclerosis may be caused by tobacco, though it is highly probable that when this condition exists, the symptoms are accentuated by it. Tobacco angina is promptly relieved by discontinuation of tobacco; no such result can be obtained in true angina pectoris. It is probably unwise to permit the use of tobacco in circulatory diseases when symptoms of cardiac embarrassment occur. The persistent use of tobacco immunizes against vagus effects and sensitizes to coronary claudication. Death may result from acute tobacco poisoning, in which case its mechanism is chiefly from vagus effects. Death may result from tobacco angina, but is probably very rare and most likely occurs only when anatomically diseased coronary vessels preexist. The essential treatment of tobacco poisoning is suspension of the use of the weed.

6. **Psychopathology of Neurosis.**—Boris Sidis presents the hypothesis that psychopathic maladies do not depend on the abnormal action of some one organ or function, but on a general condition common to all bodily and mental functions, viz., the fundamental primitive fear instinct which relates to life in general. The deranged functions, cardiac, respiratory, or sexual, fatigue, conflict, shock, are only the occasions. To regard any of these occasions as the source of psychopathic maladies is like regarding the weathercock as the source of the wind. The fear instinct alone is the source of all psychopathic maladies.

10. **Syphilitic Aortitis.**—J. Epstein details as follows the symptomatology of this condition: (1) Palpitation of the heart or an irregular unpleasant throbbing along the sternum, worse on exertion or excitement. On examination of the heart there is usually no enlargement, no changes in the cardiac sounds, no tachycardia, and no murmurs. (2) Attacks of angina pectoris. These may have their starting point in the sternum or in the precordial region. They radiate thence backward or upward and along the arms. The anginal pain may also begin in the left hypochondriac region and radiate upward. (3) Persistent pain in the left scapular region. This pain is usually attributed to rheumatism by those physicians who call all kinds of obscure aches and pains rheumatic. (4) A peculiar almost characteristic hoarseness of the voice, when once heard, is sufficient to attract the attention of the physician. (5) A persistent cough which has a certain croupy, dry, and harsh quality, and occasional attacks of dyspnea. On physical examination of the lungs one finds stridulous respiration, but nothing else to account for the cough. A patient of mine was treated for some time by his family physician for chronic bronchitis and asthma, when on examination I found an aortitis to be the cause of the cough. The cardinal signs or evidences of syphilitic aortitis are: (1) Increased episternal dullness. (2) Increased radiographic shadow of the aortic arch. (3) Positive Wassermann test of the blood or cerebrospinal fluid. Careful percussion along the manubrium sterni will elicit an increased area of dullness to the right or left of the sternum or on both sides. An *x*-ray is indispensable in these cases; it shows an enlargement of some part of the thoracic aorta. A positive Wassermann test of the blood or if necessary of the cerebrospinal fluid completes the diagnosis.

1. **Aseptic Technique.**—G. E. Brewer reviews his studies of this subject beginning with 1895, when 39 per cent. of all clean operative wounds occurring in his service in the City Hospital became infected, and continued to the present time, when the percentage of infection is less than 0.2 per cent. in the author's service in the Roosevelt Hospital. The poor results in the early days were explained by the absence of a suitable modern sterilizing autoclave, the inefficient preparation of ligature and suture material, and the lack of training on the part of the house staff and operating room nurse in modern aseptic methods. Among the factors in the recent improvements are mentioned the following: Whenever possible a tub bath was given to the patient the night before operation, followed by shaving the wound area, and the application of a soap poultice. After from four to eight hours this was removed, the part scrubbed with soap and hot water for five minutes, and a wet mercuric chloride dressing applied. On the operating-table this dressong was removed by a sterile assistant, the parts rescrubbed for one minute, douched with ether, alcohol, and a 1:5,000 solution of mercuric chloride. The wound area was surrounded by sterile towels, and the entire body covered by sterile sheets. Sterile caps, gowns, and gloves were worn by all participating in the operation. The towels around the wound area were changed as often as soiled, and always before the insertion of the cutaneous sutures. The

technique was changed slightly in two classes of cases, operative treatment of fractures, and open operations on the knee joint. In these cases face masks or helmets were worn, and nothing entered the wound which had been touched even with the gloved hand, all manipulations being carried out by instruments. More recently the long-sleeved operating gown has been introduced.

3. **Contour of the Normal Arterial Pulse.**—C. J. Wiggers concludes that the pulse, as palpated or recorded from any artery, is the variation in the arterial volume producted by the intra-arterial pressure changes at that point. The details of the arterial pulse correspond exactly to the details of the pressure curve. To record these variations requires an apparatus of higher efficiency than is supplied by any form of apparatus in current clinical use; hence, the details of these changes were not recognized until the introduction of the segment capsule of Frank. The contour of the central pulse differs materially from that of the peripheral pulse. The former allows an exact study of the pressure changes in the large central arteries; the latter records these changes as modified by friction and waves reflected from the periphery. The central pulse offers exceptional opportunities for studying the condition of the circulation. A study of its contour during systole permits conclusions as to the relations between cardiac output and peripheral flow offered by no other method. The precise onset of systole and diastole can be accurately determined.

9. **Roentgenization of Thymus in Graves' Disease.**—C. A. Waters finds that roentgenization will cure, temporarily at least, some cases of Graves' disease. It will effect an apparent cure in some cases of hyperthyroidism when other measures have failed. Intensive irradiation under strict and rigid technique has no bad or ill effect on patients with Graves' disease. Evidence enough is at hand to warrant a more liberal employment of this treatment.

11. **Tissue Extract as a Hemostatic.**—A. F. Hess has employed as an efficient hemostatic tissue obtained fresh from the slaughter-house, washed thoroughly free from blood, ground up in a machine, extracted in salt solution in the refrigerator and then filtered. In its preparation, aseptic precautions are observed as far as possible. The extract, which contains some fine suspension of tissue in addition to tissue juice, is made up with 0.3 per cent. of trikresol and preserved in this way. Aerobic and anaerobic cultures of this fluid have been found sterile. In addition to this liquid preparation, a powder has been prepared—the tissue has been desiccated and then finely ground up in a mortar. Thromboplastic preparations treated with this small percentage of trikresol have been found to maintain their potency for at least a month. The author has employed the tissue extract in two cases of persistent bleeding in hemophilia. In each instance the bleeding ceased at once and did not recur.

1. **Wound Infections.**—Sir A. E. Wright in the second installment of his article on this subject discusses the emigration of leucocytes into the wound. He has evolved a laboratory method for the study of the phenomena of emigration. The most important part of this method consists in the use of flat capillary tubes containing centrifugalized blood. It was found that white blood corpuscles will move out in any direction towards a chemotactic substance. They will, however, emigrate more freely downwards, than horizontally; and more freely horizontally then upwards. Anaerobic conditions are more favorable to emigration than aerobic conditions. Leucocytes will travel out further in the direction of a chemotactic substance when we absorb the oxygen in the tube with caustic alkali and pyrogallic acid and seal, than when we leave the end of the tube open to the air. Leucocytes emigrate more abundantly in tubes standing at a temperature of 40 deg. C. than in tubes standing at 37 deg. They do not emigrate at temperatures of 10 deg. to 15 deg.—the temperatures which prevailed on our laboratory bench. After exposure to temperatures of 0 deg. C. for periods of half to one hour they emigrate apparently as freely as before. Emigration apparently goes on unaffected in the presence of ether. It is abolished or suspended in an atmosphere of chloroform. Physiological salt solution, brought into application either by traversing or by superimposing it upon the clotted or unclotted blood, induces a very vigorous emigration of polynuclear white blood corpuscles. Weaker salt solutions induce a less vigorous emigration, and water again a less vigorous. Strong salt solutions—for example 5 per cent. salt solutions—suppress emigration. Bacterial suspensions which have been sterilized by heating evoke, according to the dilution in which they come into application, quite different effects. The general rule applying to bacterial suspensions would seem to be as follows. Concentrated suspensions usually completely suppress emigration. Ten or hundredfold diluted, these same suspensions evoke vigorous emigration. When we employ progressively higher dilutions we arrive in time at a point when the effect of the bacterial suspensions is exactly the same as those of the articular fluid which we are employing as a diluent.

3. **New Theories of Pellagra.**—A Cencelli, President of the Pellagra Commission of Rome, points out that numerous investigations have shown that maize can no longer be regarded as the sole and specific cause of this disease. The English commission, with L. W. Sambon at its head, has put forward the hypothesis that the disease must be attributed to a parasitic protozoon, which is probably transmitted and propagated by a species of mosquito (simulium) existing in the drinking water. The latest investigations are those of Alessandrini and Scala, according to which pellagra appears to be a chronic poisoning brought about by the silica in colloidal solution in waters of determined composition; in other words, pellagra seems attributable to mineral colloids. According to the authors the clay is the first cause of the evil, for the rain water present, either in the superficial or the deep strata of the ground, reacts upon the clay which is a silicate of alumina, producing a hydrolysis that brings about the formation of silicic acid and hydrate of alumina. Both these compounds, from the condition under which the hydrolysis takes place, can pass into the water in the colloidal form. Since, as is well known, there exists an incompatibility between colloidal silica and colloidal alumina, there only remains in the water the amount of silica in excess of that required for the precipitation of the alumina. The colloidal silica-alumina compound, which must on no account be confused with silicate of alumina, goes to form the deposit. Part of it, however, remains in suspension as a very finely divided colloid, and is the cause of the persistent opalescence often observed in the water drunk by sufferers from pellagra. The poisoning by silica would thus resolve itself into a

mineral acidosis upon which would depend all the anatomical, pathological, and metabolic alterations which are met with in pellagra patients. Hence arose the other conclusion regarding pellagra—viz., that it is a disease due to the enforced retention of mineral salts followed by a liberation of acids which is excessive in comparison with the amount regarded as normal in the case of any given organism. It having been proved that the question is one of mineral acidosis, Scala and Alessandrini believed that the toxic effects could be modified by the injection of an alkaline substance such as trisodium citrate. The author also offered the suggestion that the pellagra inducing water could be corrected and freed from the supposed injurious substances by placing small pieces of lime in the pipes and reservoirs.

4. **Acute Abdominal and Acute Intrathoracic Diseases.**—C. Mackenzie states that severe abdominal pain, often accompanied by vomiting, rigidity of the muscles, and even localized tenderness, may exist without any lesion of an abdominal viscus. When possible it is advisable, therefore, to examine the thoracic viscera before submitting a patient to laparotomy. A thorough examination is frequently impossible owing to the condition of the patient, but in all cases the pulse-respiratory quotient can be analyzed and considered with the temperature. The author considers this quotient to be of the utmost value, and if attention be paid to it he does not think many cases of pneumonia will be treated by abdominal section. With regard to pleurisy and pericarditis, reliance cannot be placed on either the quotient or the temperature, and as in the past so in the future will mistakes occasionally occur. In all very acute abdominal cases, where the general peritoneal cavity is involved, tenderness is usually elicited on rectal examination and actual swelling is often found; a rectal examination should therefore be made in all suspected acute abdominal conditions. In doubtful cases the history of the onset should be considered, as pericarditis is usually preceded by tonsillitis or pains in one or more joints. When the abdominal signs are so serious that one concludes that if the disease is abdominal the condition is so severe that surgical procedure offers the only hope, then laparotomy should be performed. Against this view is the fact that if the case is due to pneumonia then harm must be done to the patient by the operation, for apart from shock, the inhalation of ether must have a prejudicial effect on the already congested lungs, and chloroform must still further embarrass a heart enfeebled by toxemia. In a case which presented such a dilemma, Mackenzie said, the safest procedure would undoubtedly be to perform the operation under some form of local anesthesia.

5. **Frostbite.**—C. Miller believes that there is no difference between the forms of so-called "frostbite" as regards causation. The differences are in the effects on different individuals, and they are merely different manifestations of the same condition. The definite physical characteristics of these "pale" feet which have been diagnosed as functional by certain observers are not such as are found in functional disorders. It can be admitted that these patients are in a condition of nervous exhaustion, but their previous hardships, to which are added pain and loss of sleep from pain, are sufficient causes for their appearance. Further, the various and sometimes very diverse effects of frostbite may not infrequently be seen in the same individual and occasionally even in the same foot. Whatever else may be discovered about this condition the author is satisfied that it is primarily physical and only secondarily psychical.

8. Acute Inversion of the Uterus Following Labor on Two Occasions. N. S. Carruthers.

2. **Blood Pressure Estimation in Children.** — G. S. Melvin and J. R. Murray employed the auditory method in forty children, varying in ages between 4 and 14 years. The average systolic pressure was found to be 108.1; the average diastolic pressure, 72.4, and the average pulse pressure, 35.7 mm. Hg. By the tactile method the average systolic pressure was 105.7 in children as compared with 108.7 in adults, while the range was 125-84 in the former and 132-92 in the latter. By the auditory method the range of systolic pressure was 130-90 in children and 135-92 in adults, while the range of diastolic pressure was 90-50 in the former as compared with 82-50 in the latter. In children the relation of pulse pressure to systolic pressure was 1:3 and to diastolic pressure 1:2, while in adults this relation was 1:2.7 and 1:1.6 respectively.

3. **Idioglossia.**—W. B. Drummond defines this as a defective condition of speech of such a nature that the affected person is unintelligible except, perhaps, to his own relatives; yet, what he speaks is really English very grossly mispronounced. The author reports a case of this condition in a boy 13 years old. The symptoms supported the view that in idioglossia the peculiar speech is neither a persistence of baby language nor a new tongue invented by the patient. The child's speech really represents a very defective attempt to speak his own mother tongue. The defect does not arise from any impediment in the articulatory mechanism; nor to want of intelligence; nor to lack of visual memory; nor to inattention, though these may be noticed in some cases; nor to deafness in the ordinary sense. But the symptoms are explicable on the theory that there is defective audition in the sense of some affection or imperfect development of the auditory word center. Idioglossia would thus come under the same class of cases as congenital word-blindness.

5. **Effects of Military Training upon Lead Workers.**—F. Shufflebotham has observed fourteen cases of lead poisoning among lead workers, chiefly pottery workers, who had enlisted in the English Territorial Forces. He suggests that the altered conditions of life, especially the muscular exercises associated with route marches and physical drill, cause increased metabolism, with the result that lead compounds previously locked up in the muscles and organs of the body become released and reach the blood stream, thus setting up the symptoms of which the men complained.

6. **Typhus Fever.**—E. C. Hort states that the most important points on which, when taken together, a positive diagnosis of typhus can be based, are: (1) The characteristic rash. (2) The smell of the skin. (3) A history of previous cases of the disease in the same house, especially if associated with lice. (4) The stuporous condition of severe cases presenting the rash. (5) The precritical fall of temperature. (6) The enormous relative and absolute increase in the large mononuclear cells in the blood. (7) The presence in blood films of the large diplobaciliary and diplococcal organisms described by numerous observers. (8) Their presence also in fresh urine. (9) The presence in

the centrifugal deposits of fresh urine of the minute Gram-positive, Gram-negative, pleomorphic organism described by Hort and Ingram. (10) The isolation and cultivation of the same organism from the blood and cerebrospinal fluid. (11) The results of injection of cultures of these organisms, or of fresh typhus blood, into bonnet monkeys.

Münchener medizinische Wochenschrift.

March 16, 1915.

Unilateral Renal Hematuria Cured by Decapsulation.—Els reports a case from Professor Garré's clinic of renal hematuria as a part of a general poisoning by cresol sulphuric acid. The author believes that so-called essential renal hematuria is always due to some preceding lesion of the organ in question—an inflammation, if nothing else. The unilateral incidences in certain cases have always been construed as evidence against a hematogenic theory. Recent reports appear to show that a true "medical nephritis" may occur in one kidney, which as a result simulates a surgical lesion, characterized by hematuria and colic. The literature of the past decade or more makes us familiar with the bilateral hematurias of hematogenous origin, and the unilateral hematurias of local origin; but not with the cases under consideration. One of these the author cites: A man, aged 33, always healthy, occupation live stock car cleaner, was seized with frequent desire to micturate and vesical tenesmus. The urine soon became of blackish red color, and pains appeared over the left kidney. The urine was that of "essential" hematuria—no renal or bladder lesions, save a mottled redress in the floor of the latter. The attacks of hematuria returned from time to time. Ureteral cystoscopy showed that the right kidney was secreting a perfectly normal urine. The author now determined to expose the left kidney. This appeared perfectly normal after removal of the fat capsule. The capsule proper was now incised and turned back, and nothing abnormal encountered. The tissues were all restored to their positions, and the wounds closed. The post-operative course was smooth and rapid, and no more hematuria resulted. The sole lesion to be found at any time was the cystitis, which was of the type seen in aniline poisoning. Now, the patient had recently been disinfecting suspicious cars with a mixture of cresol, sulphuric acid, and water. One kilogram of disinfectant (cresol 2, acid 1) was added to 60 liters of water. After having sprayed the cars with this fluid, the patient noted that his urine and breath had acquired the smell of the disinfectant.

The War as Studied by a German Surgeon through Hostile and Neutral Medical Journals.—We have already given excerpts from the articles of Professor Madelung which are based on a survey of prominent medical periodicals in France, England, the United States, etc. The testimony is very conclusive that in war times aseptic surgery falls short, and that we may have to return to the antisepticism of Lister. Nevertheless, adherents of the latter view are in the minority thus far, although they comprise men like Watson Cheyne in England, and Doyen in France. A middle ground will probably be reached which will insist upon antiseptics for certain classes of wounds, at least. Of 2,000 British wounded in one hospital nearly all became infected. Would early antiseptics have prevented such ravages? The Paris correspondent of the MEDICAL RECORD states that every French soldier is provided with iodine for his kit, so that he may apply immediate disinfection when he is not too badly wounded. Contrary to an early impression that the German soldier was more commonly attacked by tetanus than his foes, the testimony of the journals of the allies implies that the converse may be true. In some French batches of wounded tetanus appears to have been the most common cause of death. The author seems skeptical concerning a statement to the effect that French soldiers now receive an immunizing injection against tetanus before entering the trenches. It is admitted, however, that immense quantities of serum are manufactured at the Pasteur Institute. The French and English appear to have been fortunate in escaping pestilences, and typhoid seems to have been almost abolished by immunization. The wonderful endurance of the Sikhs is quoted. These Hindu soldiers can far outmarch any Europeans. In closing the author quotes from a MEDICAL RECORD editorial which expresses the hope that the medical lessons learned from the war hospitals may even be of such magnitude that in time to come they may offset the vast losses of men. In expressing the same hope, the author states that thus far such benefits have not come into evidence.

Münchener medizinische Wochenschrift.

March 23, 1915.

The Diphtheria Bacillus.—Several authors contribute articles on various aspects of the Klebs-Löffler bacillus in the present number. Plange and Schmitz discuss its occurence and distribution in the human body. On this subject authors differ widely, finds being based on autopsies. The present writers have made numerous autopsies quite recently, and a distinction was made between tracheotomized and non-tracheotomized subjects. In the latter bacilli were formed in the throat, nose and lungs in varying percentages, none higher than 40 and 14.3 per cent had the bacilli in the suprarenal glands. In tracheotomized cases bacilli were found in the adrenal in 100 per cent, in the throat and trachea in 85.7, nose 66.7 and lungs 60 per cent. In the spleen, liver and kidneys they were found in 28.6 per cent each; in the bile in 25 per cent and finally in the heart blood in 16.7 per cent. It is evident therefore either that tracheotomy mobilizes the bacilli, or that the operation is performed most frequently in cases of general bacillosis. The authors appear to accept the last view. Dr. Rall writes briefly about bacillary finds in the herpes febrilis which occurs in about 7 per cent of all cases of diphtheria. The author has tested these vesicles extensively for bacilli and their characteristics. He has found them to contain bacilli in a large proportion of cases, irrespective of the degree of severity. Therefore there is no prognostic significance to be attributed to them, nor is it likely that they assist much if at all in the propagation of the disease. The bacillus does not cause the eruption of vesicles but finds its way into them, along with other more familiar bacteria. They probably enter the vesicles in ordinary herpes of the nostrils by direct contamination with nasal secretions. In more remote localities the transmission must be effected by the lymph or blood stream. Engelmann writes briefly on bacillus carriers, whom he believes to carry the virus in the nasal fossi under varying conditions. Recently a child died of the disease and the author examined four other children of the family who were of the school age. In three the nostrils showed hardly any soreness. The other had no soreness whatever at the nostrils but one tonsil was slightly reddened, and at one crypt there was a barely visible point. This child in fact had a minimal case of faucial diphtheria. The nasal secretions were now examined and in all 4 children contained an abundance of diphtheria bacilli, which, however, were nonpathogenic. The children were in excellent general condition and doubtless will soon cease to be carriers.

Insurance Medicine.

What Significance Has the Wassermann Reaction for Life Insurance?—Blumenthal states that this subject has been discussed in the *Blätter* from every angle. All authorities are agreed that it is in the highest degree desirable to possess a trustworthy reaction for syphilis, for the latter is widely diffused among all strata of society, to an extent even greater than pessimists themselves have believed. An objective blood reaction for syphilis is specially desirable for the applicant for insurance does not always intentionally deceive when he denies syphilis. But the sufficiency of the test in life insurance has been widely debated. To clear up the controversy we need statistics, and the author herewith contributes the results of thousands of tests made at the dermatological clinic at Charity Hospital, Berlin.

The reaction is important in two directions, one of which concerns the diagnosis of former syphilis, while the other has to do with prognosis.

What is the relative value of positive and negative tests? The great value of the former is undisputed. The author has never seen a positive reaction in a healthy subject, although it may be encountered in victims of various diseases which are hardly to be thought of in connection with life insurance, since they render the subject even less insurable than a syphilitic (malignancy, leprosy, gland tuberculosis, leucemia, malaria). Hence this component of Wassermann positives can be left quite out of consideration.

The negative reaction is much less trustworthy, for it is seen at times not only in suspicious but also in undoubted cases. In latent cases in which there is no clinical evidence of syphilis the positive Wassermann is present in only 60-70 per cent. of cases. It could, of course, be assumed that the remainder were permanently cured, but experience teaches that many of these will certainly relapse. Many of those who deny syphilis falsely may be apparently corroborated by the negative Wassermann. It is also possible for a syphilitic to undergo an intensive cure for syphilis until he reacts negatively, and then apply for life insurance. This is one of the weightiest reasons advanced against the introduction of the reaction.

There is, however, the second phase of the problem, the prognostic. Some of the worst consequences of syphilis, such as paresis, aortitis, etc., can never be so influenced as to give a negative reaction, and deaths from these causes can be eliminated by the Wassermann.

Various other problems confront us in regard to the general adoption of the reaction. If an applicant who is ignorant of his syphilis is enlightened by the result of the serological test, he is able to seek a cure, and is really under obligation to the company. He may not, however, feel that way about it. Again, many applicants might be deterred from undergoing this simple test, on account of ignorance of its nature and the fear of ill consequences.

Finally of great significance is the possibility of rendering positive Wassermann cases insurable by frequent tests, the applicant in the meantime undergoing treatment. Those finally rejected are rejected on ample grounds. Not only actual but suspected syphilis would be dealt with in this manner (habitual abortion, leucoplakia, etc.—*Blätter für Vertrauensärzte der Lebensversicherung*, 1914. Nov.-Dec., No. 6.

The "Copenhagen Heart."—Dr. I. A. Hielscher of Mankato, Minn., writes concerning an effection to which he applies this term, brought about by the habit of taking Copenhagen snuff. This habit prevails in the Northwestern States, he says, and by reason of the great influx of Scandinavians, Danes and Finlanders into the States of Michigan, Wisconsin, Minnesota, and North Dakota, it has received a marked impetus until at the present time it has become a menace to the younger generation of native-born Americans.

For many years the above-named nationalities have been heavy users of snuff as a sternutatory, but of late many have resorted to a form of use similar to "dipping," which consists in placing a pinch of snuff in the mouth. The habit has spread rapidly until at the present time it is almost general among the younger working men and factory hands in the cities, and is also gradually finding its way into the rural communities.

The method of using Copenhagen snuff is somewhat unique: A small portion of the moist article is taken up by the fingers, rounded into a pellet, and placed under the upper or lower lip; here it is retained until the effects wear off, then another pellet is moulded in the same manner and placed in position. In this way some of the habitués consume as much as a box per day. Snuff used after this fashion does not require mastication, nor does it stimulate the salivary glands, hence there is complete absence of expectoration. Whatever action it has on the system must be produced by absorption through the mucous membrane of the buccal cavity.

Heilscher in his capacity as examiner for various fraternal life insurance companies, frequently found peculiar symptoms for which he could ascribe no definite cause. For example, a young robust looking laboring man makes application for membership and reports for examination. In filling out the blanks everything is satisfactory, the physical examination progresses nicely until the heart is reached. Here is found the stumbling block. The pulse is rapid, 80 to 90 beats a minute, hard in quality, and high in tension; the cardiac area is normal but the sounds are rough and harsh. Upon the slightest exertion a blowing mitral regurgitant murmur develops, there is marked shortness of breath, and if questioned more closely, the applicant will complain of palpitation at night, while lying quietly in bed. The blood pressure in these cases is, as a rule, high.

There are also frequently other symptoms to be observed in young laboring men whose age and outdoor occupation should have insured them good health. These symptoms are headache, vertigo, shortness of breath, nervousness, loss of memory, loss of appetite, trembling of the hands, and in some cases a "dopy" appearance, with a general downward tendency, mentally, morally, and physically, leading in some cases even to the verge of dementia.

The conclusions of the writer are as follows: The symptoms of a snuff fiend are these: A mitral regurgitant murmur upon the slightest exertion, high blood pressure, shortness of breath, headache, sleepnessness, dizziness, trembling of the hands, a "fishy" stare, indigestion, loss of weight, and in many cases, if they are very heavy users, a "dopy" look with sluggish mental condition.—*St. Paul Medical Journal*, March, 1915.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

109th Annual Meeting, Held in Buffalo, April 26-29, 1915.

(Special Report to the MEDICAL RECORD.)

SECTION ON SURGERY.

(*Continued from page 754.*)

Cancer of the Breast.—Dr. PARKER SYMS of New York gave an account of the breast operation for cancer. He said Charles More in 1867 first described carcinoma as a localized process. It was possible then to eradicate it. Harold Stiles of Edinburgh further studied the lymphatics, the morbid and surgical anatomy of the breast. Twenty-one years ago the real operative work began with Halsted of Hopkins and Willy Meyer of New York. At first Halsted's work predominated. To-day most operations were done according to Meyer. Meyer cut vessels across at axilla and worked downward and outward. It was pointed out that carcinoma spread by permeation from the periphery of the growth and in one direction as far as another. Therefore it was necessary to carry incision down through the rectus sheath. It was pointed out that the skin area was not as important as the depth undermined. Slides were shown to illustrate the technique. Jackson's operation was not recommended because turned down skin flap often overlay the tumor itself. The flap should be removed. Rodman's operation began with an incision from the midpoint of the clavicle. Its advantages were the early knowledge of the degree of glandular metastasis and the freedom of the axilla from cicatrix following the operation. He worked toward tumor, not toward the axilla. Operations were said to be accompanied by little shock, slight blood loss, and speedy recovery. Diagnosis should be made at time of operation largely on appearance of gross specimen. The findings from a frozen section were said to be misleading.

A New Operation for Cancer of the Rectum.—Dr. EDGAR R. MCGUIRE of Buffalo said progress in rectal surgery for carcinoma was hampered by pessimism. This should be dispelled. The evidence ascertained by the gloved finger in the rectum and bloody mucus from the rectum were important for diagnosis of cancer. Believed an effort should be made to preserve the anal sphincter. This was especially disregarded in cases of cancer of the mid-rectum. Charles Mayo recommended saving the distal one inch of the rectum. The sphincter should be freed of its mucosa. The intestine should be cut across and the cephalad end sutured to the rectal stump, coapting mucosa with skin. Stretching of the sphincter at times caused a four weeks' postoperative incompetence.

Dr. HARVEY R. GAYLORD of Buffalo pointed out the fact that it took many years for laboratory facts to become the property of the general practitioner. The manipulation of cancer he said, caused a change in its character. There was an immunity to cancer that caused animals to act differently toward cancers and cancers to behave differently in different animals. Certain malignant tumors when transplanted become benign but when transplanted again become malignant. Clinical history should accompany section sent to research laboratory for an accurate prognosis. Classifications of tumors, such as Dr. Barber's, should give way to studies of the life histories of carcinomata. Actively growing cancers provoke marked immunity in animals. They have to be reinoculated or the growth became lost. It was shown at the Rockefeller Institute that sarcoma in fowl was caused by virus of three different kinds.

Dr. JAMES A. GARDNER of Buffalo held Squier's resection gave marked improvement over simple incision for cancer of the bladder. Resection recurred in 43.7 per cent. and excision in 88 per cent. after three years. Mortality of Squier's or Mayo's operation was 10 per cent. Cauterization should be confined to pappilomata.

Dr. JAMES F. PERCY of Gainesville said there was no question of the efficacy of radical surgery. The knife could not be used in a great many cases however. He said you might treat a cancer patient with the knife in one hour but not with radium or the *x*-ray. In these prolonged treatments, the patient absorbed the broken-down cells. He recommended the use of heat to convert inoperable into operable cancer. He pointed out that intense heat penetrated ⅛ to ¼ of an inch while heat to 180° F. penetrated 3 inches.

Dr. PARKER SYMS reported a case treated similarly to Dr. McGuire's. He operated by the continued method removing 14 inches of intestine. Sloughing followed operation. Rectal incontinence had continued. He removed fat and lymphatics as high as possible. He advised Meyer's radical breast operation for all suspiciously malignant tumors of the breast.

Wednesday, April 28—Second Day.

Subacromial Concretions.—Dr. WILLIAM W. PLUMMER of Buffalo included in his discourse the subject of bursitis. Pain, stiffness, and limitation of abduction and rotation were explained by the anatomical connections of the bursa to the humeral head and its relations to the acromion. For there was an infolding of the bursa between the greater tuberosity of the humerus and the acromion process. This was impinged upon in extended abduction. The causes of bursitis were given as trauma, induced in any way, tuberculosis, and infection. Under pathology Dr. Plummer mentioned effusion of serum into the joint, adhesions within the joint, and lacerations of capsule and tendons, especially the supraspinatus tendon. Since salts were deposited within the joint cavity as thickenings of the capsular membrane or as deposits within muscular fibers. He held two distinguishing characteristics of bursitis to be (1) a radiogram showing absence of fracture, and (2) joint tenderness elicited by longitudinal pressure through hand and arm, with arm in extended position. He did not believe a thickened bursa without lime deposits was visible by *x*-ray. He treated his cases by rest, forcible abduction under gas which was sufficient in some cases, or operation for removal of concretions and repair of lacerations. He exposed the joint by splitting and retracting fibers of the deltoid. Lime was often found in tendon of supraspinatus, often about tendon or lining capsule. In the author's experience the abduction method was the most valuable postoperative treatment. He showed a number of slides, showing (1) Concretion in bursa. (2) Joint of man of 20 years injured in wrestling, with limited abduction and local tenderness, and fluid and adhesions. This case had lacerated tendon repaired and was well after three months of abduction. (3) Concretion in bursa resulting from a fall from a carriage. This case, refusing operation, continued to suffer pain for six months. (4) Case with productively inflamed supraspinatus tendon and adherent thickened capsule with extensive villous formation. He was treated as a fracture case without having had an *x*-ray for six weeks, but promptly got well after removal of inflamed capsule. (5) Concretion in shoulder bursa which could be palpated and of seven years' duration without recognition. (6) Concretion, which was later removed. (7) Lime deposit in bursal floor. This case was free from pain after three months of postoperative treatment. (8) Concretion in bursa. In conclusion believed stiff, painful shoulders were relieved by operation.

Dr. MEISENBACH of Buffalo said he believed all stiff shoulders should be carefully studied because their etiology was often obscure. They might be due to infection or to a disarranged metabolism or to a ruptured supraspinatus. Supraspinatus worked in harmony with the deltoid and besides had the function of withdrawing the bursa from the joint. He recommended operation, especially in ruptures of the supraspinatus. He differed from the reader by holding that thickened bursæ were impervious to the rays and could be demonstrated occasionally by *x*-raying the shoulder with the arm at rest and in the extended abducted positions.

Dr. F. H. ALBEE of New York believed in hanging to a strap on a street car was a possible cause of bursitis.

Dr. SAYRE of New York declared that he had seen concretions in the shoulder joint in *x*-ray pictures of the shoulder with the arm in different positions. He believed the bursa was pinched oftentimes by simply raising the arm. He had experienced such a result himself.

Reinforcing Paralytic Flail-Joints by Intraarticular Silk Strands to Limit Motion and Increase Stability.—Dr. BERNARD BARTOW of Buffalo emphasized the importance of holding the articular surfaces of joints closely together by silk strands. This applied to the shoulder, knee, hip, ankle, and pelvis. He demonstrated a drill which he used to pass his silk supports. In the knee they were placed two anteriorly and two posterior-

ly. In the hip strands were directed from acromion rim down on to head of femur. It was often difficult in the ankle to adequately immobilize it. Although some surgical reaction followed the use of these measures a protecting soft bandage over the affected joint and rest in plaster were all that were necessary for relief. He usually put them up in the right angled position and encouraged early use of muscles. He said his method should be considered as an attempt to produce a better functionating joint than the flail joint. It was simple, incisions being small and much of the work being subcutaneous. The joints were not mutilated nor were muscles jeopardized. Ankylosis did not result. In the 150 cases so treated at the Children's Hospital no mortality or infection resulted.

The Phenomena of Acidosis and Its Dominating Influence in Surgery.—Dr. GEORGE W. CRILE of Cleveland discussed the significance of acidosis. Acidosis existed whenever the acidity of the urine was higher than normal. There were many such cases, but the physician saw them only in the breakdown stage. Lawrence Henderson of Boston deserved mention among the workers in this field. The liberation of energy was attended by the production of acid. Similarly in the vegetable kingdom the freeing of energy was attended by acid production. This was washed away by the rain. Hence the fertilization of the soil was largely a problem of alkalinization of the soil. Man depended upon the removal of acid by the liver and the kidneys. When this was not properly performed, or when the acid content of the blood appeared greater than "neutral" death ensued automatically. It was difficult experimentally to force an acid reaction to blood or spinal fluid. Whatever produced exhaustion as exertion, emotion, or toxemia, diminished the alkalinity or raised the H-ion content of the blood. Whatever activated the kinetic system increased aciduria. These changes went on within the body organs, including the liver, brain, and kidneys, and threw increased acid into the urine. Dr. Crozier had originated a method of determining this urine acidity and determining its excess of normal. Hence the extensive uses of water and sodium bicarbonate were important. The symptoms of acidosis were increased respiration, thirst which follows running fever, and emotion, and rapid pulse. The phenomena of acidosis were the efforts of the body to neutralize the acidity of the blood. They were seen in psychic vomiting, a straight acidosis, Bright's disease, Graves' disease, surgical shock, as well as in the fatigue of the athlete. All the anesthetics, especially ether, less chloroform, least nitrous oxide, produced increased blood acidity. Starvation produced acidosis. He showed numerous slides depicting changes in the cerebellum, liver, and adrenal gland, supposed to result from acidity following fatigue, emotional excitement, shock, anesthetic, and toxemias. Indol and skatol were included among the toxins, thus establishing the communication between intestinal stasis and brain changes.

Dr. H. L. TAYLOR of New York declared Crile's work to be full of meat for the clinical surgeon and physician as well as the technician in the laboratory. He reported three cases that died of acidosis in his hospital service. These included a postoperative, an etherized case, and one for whom nothing had been done. He held intestinal purging was not as important a prerequisite to orthopedic as in abdominal surgery.

Dr. M. TINKER of Ithaca said he had long appreciated the acetone odor to the breath and the increased urine acidity in goiter cases, and given bicarbonate of soda. He reported a duodenal ulcer case with complete gastric intolerance. He managed to improve patient enough to operate. After operation he improved enough to take food by mouth before succumbing. This was a case of acidosis.

Dr. O'NEIL asked whether acidosis should be considered a contraindication to operation or neutralized and disregarded.

Dr. J. D. BONNAR of Buffalo asked whether acidosis had a direct effect upon the centers or whether it was transmitted, and how much exercise should be advised.

Dr. SORESI of New York brought out the toxic effect of bicarbonate of soda upon the red blood cells, and wondered whether Dr. Tinker's patient might not have died as a result of such a toxic effect.

Dr. CRILE again mentioned the urine acid test as a means of determining acidosis cases. He advised anoci-association and plenty of water. He contended exercise should be undertaken in moderation.

Mechanical Respiration Prior and Subsequent to July 23, 1887.—Dr. GEORGE E. FELL of Buffalo said there was no thought of vivisection to save life before 1887. All physicians at that time were opposed to innovations. He showed the bellows which was the apparatus ordinarily used to save life in the vivisection laboratory. He then showed his original apparatus by which he saved his first human life. He declared he had labored ten years gratuitously. His first patient had cyanosis, rigidity, and dilated pupils before connecting up his apparatus to save him. A second case was reported in Austria saved by an improvised apparatus. His third case had had the Sylvester method tried to no avail before his attempt. It then required twenty-one hours of continuous forced respiration. He reported a fourth case in which the man had cut his throat and arm, and swallowed two ounces of laudanum before he eventually saved him. During the past six months, he said, he had saved four adult lives. His last attempt, upon an eighteen months baby who had previously received a grain of morphine, was unsuccessful.

Dr. CRILE assured Dr. Fell his principles had been received by the physicians long ago, if not by the laity. Fell as an historian and a philosopher must have derived considerable satisfaction in seeing his efforts appreciated by others all over the world. He was said to be to artificial respiration what Fulton and McCormack were to their lines. They, like Fell, would have thought their work to have been in vain had it not been improved upon by others.

Dr. BATES of Buffalo knew Dr. Fell for many years. He knew him when a United States engineer and when a professor of physiology. He read an editorial written by George Matthews for the Buffalo *Morning Journal*, January 27, 1888, entitled "He Shall Not Labor in Vain." This was written in appreciation of the saving of a life.

Letters were read from Drs. WILLY MEYER of New York and A. J. OCHSNER of Chicago. Dr. Ochsner claimed he had used Fell's apparatus with and without the facial mask, and that all credit belonged to Fell.

Dr. DUNNING of New York declared he had labored with Fell and hoped some monetary appreciation might be forthcoming as a provision for him in his remaining years.

Dr. FELL in conclusion said that he felt amply repaid for all he had done. He demonstrated some of his apparatus.

Military Gunshot Wounds. — Col. CHARLES RICHARD defined gunshot wounds so as to include wounds caused by rifles, hand grenades, bombs, and the aeroplane shaft. He pointed out that the resistance offered these missiles determined the amount of injury. Diaphyseal wounds were therefore more severe than epiphyseal. The rifle bullet caused a penetrating wound which usually healed by first intention. The opening of departure was larger than that of entrance to the body. Dum-dum bullets from the town of Dum Dum in India were bullets with cylindrical cavities bored in pointed ends. They flattened on contact and created jagged wounds. Shrapnel caused contusions and carried particles of clothing into the body. These wounds usually suppurated. Emergency treatment was fixation only. No examination or operation was considered justifiable.

Election of Officers.—This resulted in the choice of *Chairman*, Dr. Harry R. Trick of Buffalo, and *Secretary*, Dr. Towns.

Dr. RICHARD supplemented his previous paper by showing lantern slides. These included pictures of the aeroplane arrow, the hand grenade, shrapnel, and the different types of wounds caused by them.

Dr. CRILE recalled his experiences abroad in the war zone of Paris and Belgium. He praised Dr. J. A. Blake's work at the American Ambulance in Paris. Patients with gunshot wounds of the head usually died or developed paralysis or Jacksonian epilepsy. He declared with the support of Professor Tufier and Dr. Carrel that no progress in the treatment of infections had been developed since 1870. Of the penetrating wounds below the base most die. The American dentists were doing good work in repairing buccal injuries. Those with chest wounds spat up blood for a time and got well. Abdominal penetrating wounds nearly always resulted fatally. He believed anoci association, water, opium, rectal injections of sodium bicarbonate and glucose, the Fowler position, and the hot pack included the means of most effectual treatment of abdominal wounds. Several complications followed gunshot wounds of the genitourinary system. Those of the extremities were essentially fractures. Dr. Carrel was studying intensively the possibilities of treatment of infections.

Fractures in the Vicinity of Joints.—Dr. CHARLES E. CALDWELL of Cincinnati said the *x*-ray laboratory bore the same relation as the dissecting room to the clinician. It differentiated dislocation from fracture. One case had the axillary artery pulled so tightly over dislocated humeral head that an aneurysm followed its replacement. Plating of these fractures was impossible and pegging split the bone. He favored fixation by manipulation. Fractures in children usually gave good results. He operated necessarily in only one case in a child. The scaphoid was best treated by extension. Whitman's abduction method was best for fractures at the neck of the femur. For the knee acute flexion was preferable, although doubly inclined plane gave good results. Tibial tuberosity might be nailed. He noticed the coincidence of myositis ossificans in several of the cases of malunion. In one such case three weeks of electric heat met with good results.

The Inlay and Peg Graft Versus the Lane Plate in the Treatment of Fractures.—Dr. FRED H. ALBEE of New York demonstrated instruments and slides. For fractures he advised palliation always and operation when not satisfied with results. The Lane plate was a breeder of nonunion, wire less so. Bone grafts by their friction stimulated osteogenesis. Wolf's law that a graft will hypertrophy and become strong enough to bear weight of the body was said to hold the tibia, after removal of bonegraft, hypertrophied for a similar reason. He said he based his conclusions upon a study of 400 cases. Of these, of which 385,390 had had autogenous grafts from tibiæ taken, no trouble followed removal of single tibial graft. Had also removed grafts from cadavers and other individuals. In the latter event he recommended preserving in sterile vaseline at 4°-5° C. All metal used should be recovered, for infection developed ultimately if not immediately. The plate should never be used for an ununited fracture for the ends were probably held too firmly to allow friction stimulation.

Dr. METZENBACK of Buffalo who said he had experimented on 200 rabbits asked if infection did not stimulate proliferation of periosteal and endosteal cells and whether a bone graft did not flourish in infection.

Dr. PLUMMER reported forty bone graft operations by the Albee method with but one technical error.

Dr. HERMAN asked if the plate did not require less time than the graft for bony union.

Dr. ALBEE replied that in one case staphylococcus infection undoubtedly caused a marked hypertrophy of a bone graft. Union with the graft, he said, was more rapid than with the plate.

The Standardization of Conditions Affecting Posture.—Dr. H. L. TAYLOR of New York spoke of the organization of the American Posture League. It arose out of the realization of the correlation of good postures and health. Its objects were to study conditions affecting good posture and to apply the results of these researches. The causes of bad posture were lack of vigor, habitual fatigue, lack of interest in good posture, and the adverse influence of fashion, clothing, furniture, seating arrangements, and occupational conditions. It was discovered that the coat was made to fit a round shouldered boy and attempted to coerce the boy into a bad posture. This was called to the attention of a clothing firm and coats were thereafter made to fit the straight-backed boy. Clothes should be supported from the shoulders and above the hips. Shoes were studied and found made without regard for the shapes or types of feet. Several types of feet were found among the thousand studied. One-third showed the foot to be on equal sides of a line from the center of the ball. In respect to this line some were inswung while others were outswung feet. The furniture committee had approved only one chair of all submitted, Dr. Mosher's kindergarten chair. It designed in cooperation with the engineers the seats of the new subway car for the Brooklyn Rapid Transit Company. In addition to these activities the league has published postural charts for use in schools, gymnasiums, and doctors' offices.

Dr. TOWNSEND of New York regretted that more were not present to have heard Dr. Taylor. He said such work as Dr. Taylor's was highly important.

Dr. ELIZA MOSHER of New York described the method of developing an improved subway seat and criticised the chairs in general use.

Certain Points in the Treatment of Club-Foot.—Dr. P. LE BRETON of Buffalo read this paper. He favored removals of "V" shaped sections from astragalus and os calcis, allowing the foot to come to a right angle. Tendons were cut and their courses changed when necessary. The feet so treated were put up in plaster. He performed astragalectomy and tendon fixation if necessary.

Dr. SAYRE transplanted muscles for paralysis only. He could not see the advantage of the anterior flap excision mentioned by Dr. Le Breton for he felt that hemorrhaphies should be sufficient.

Dr. TAYLOR declared he did not operate upon babies. In cases of four years or over he removed a "V" flap from the side of the foot, including the os calcis, astragloid, and scaphoid and performed whatever plastics upon the tendons and fascia as were indicated.

Dr. LE BRETON said he favored the removal of individual wedges from individual bones in order to conserve the articular surfaces.

The Treatment of Rigid Rotary Lateral Curvature of the Spine by a New Brace.—Dr. SAMUEL KLEINBERG of New York mentioned the advantages of the new brace. He said they allowed the wearers to walk about with less discomfort, to eat, drink, and to attend school. The chests might be inspected and jackets readjusted. The cases favorable for treatment with jacket were (1) single curve, (2) long dorsal and compensatory curves, (3) S-shaped curve and (4) curve in dorsal region. The results depended upon (1) nature of deformity, (2) length of deformity, (3) location, (4) severity, and (5) type of deformity. He had treated congenital malformations in 9 boys and 20 girls and got slight improvement in 8, marked in 11, no change in 3, and suspension of treatment in 6.

Dr. SAYRE considered Dr. Kleinberg's brace more applicable than the plaster jacket.

Dr. PRINCE of Rochester stated that in scoliosis 90 per cent. showed foundational defect in the lumbosacral region. No one could tell at the present time whether these patients should be held in plaster or braces; he did not attempt treatment in cases with foundational defects. He had forced at least one patient to endure a treatment for two years without success.

Dr. FRAUENTHAL of New York believed the jacket better for mid-dorsal curvature.

Dr. TAYLOR of New York thought congenital deformity was not serious in the majority of cases, and said a slight degree of lateral curvature was not a serious handicap to treatment.

Dr. KLEINBERG concluded by reporting four cases of six in which he had noted improvement after one month's treatment. All wore plaster corsets and exercised conscientiously. He had examined by *x*-ray many dorsal curvatures and found no defect in the lumbosacral joint.

Thursday, April 29—Third Day.

Intestinal Stasis.—Dr. ALLEN A. JONES of Buffalo read this paper. He considered stasis from the general aspect and as an introduction to those who were to follow. Stasis, he said, might be acute or chronic and confined to the small or large bowel. Intussusception, hernia, valvulus, foreign bodies, ulcer, cicatrix, and peritonitis were some of the causes of acute stasis, while chronic peritonitis, bands and kinks, and intussusception comprised a few of the causes of the chronic form. The symptoms of acute stasis were abdominal pain, vomiting, and palpable tumor or peritonitis. Pain was often severe. Three or four days elapsed before fecal vomiting. Constipation, he said, was the rule, though the colon was free to empty itself. There was indicanuria. The leucocyte count offered no important information. There was exhaustion and pronounced odor to the breath. He held it useless to attempt reduction of a jejunal intussusception. The illogical intussusception was most readily palpable. He believed the toxic agent to have come from the duodenum, but whether from the duodenal cells themselves or bacteria he did not care to state. Appendicitis was considered easy of diagnosis and the tuberculous form should be eliminated if possible. Under chronic stasis carcinoma should be thought of. He pointed out that it was the rectum and not the high annular carcinoma that gave consistence and form to the feces. The coincident pain was generally variable though often severe at first and absent terminally with the stretching of the walls of the intestines. There might be vomiting. The symptom complex of chronic stasis arose from complete obstruction of the duodenum, jejunum, or ileum. This was due to duodenal ulcer, appendicitis and peritonitis. The postoperative form was due to paralysis of the bowel, cauterization, and peritonitis. In event of ileac stasis there were nausea, vomiting, and constipation, which

might have existed for a long time. There were also headache, insomnia, and bad dreams, due to toxic absorption. There might or might not be an associated caloric ptosis. As a factor in toxic absorption, an incompetent iliocecal valve should be mentioned. He said the stomach and small bowel, including the terminal ileum, was normally completely empty after a bismuth meal in six hours. Stasis most commonly occurred in the colon and was due most often to caloric ptosis. In his cases the colon freed itself of bismuth in thirty-six to forty-eight hours when normal, and from that time to seventy-two hours or over when static redundancies and dilatations occurred in the ceca and sigmoids with toxic effects. In colonic stasis there were interference with the splanchnic circulation, impairment of the colonic musculature, associated appendicitis, and disturbances in the other abdominal viscera, with the unhappy reflex effect upon the mind. Backache, too, was common. Old age, invalidism, and neurasthenia were sequelæ. Not until after rest, mechanotherapy, and other medical means had failed was surgical intervention deemed desirable.

Intestinal Prolapse and Adhesions. — Dr. HENRY W. BETTMANN of Cincinnati said that before 1900, the subject of prolapse and adhesions was studied by the internists only. Glenard had invented the term to describe a descent of the transverse colon stomach and right kidney. There were six points of possible acute angulation, including the gastroduodenal, the duodenojejunal, the heptic and splenic flexures, the midtransverse colon, and the sigmoid. The hepatic flexure was the first to prolapse and dragged with it the liver, kidney, and spleen. Fullness, eructations, constipation, drowsiness, and insomnia followed. They were most common in women with relaxed walls due to pregnancy or wearing the corset. It was also said to be common in adolescent chlorotic girls. In 1896 Stiller gave his view of visceroptosis. He described the habitus enteropticus as a nervous type of an individual with small bones, a narrow thorax, and a thin fat layer. In such a case the subcostal angle was 60 deg. instead of 120 deg. in the normal individual. He mentioned the lines from zyphoid to umbilicus and from umbilicus to anterior axillary line, and held that the former was the greater in the enteroptotic but less than the latter in the normal individual. The symptoms were present or absent. Early there might be atonic dyspepsia. Later the motor symptoms of headache, backache, appeared. Neurasthenia came late. The treatment included gymnastics, bandage, and massage. Since 1900, which might be called the second period, information was increased by the *x*-ray, which drew attention to the incompetency of ileocecal valve and colonic statis, and by the orthopedists, who have pointed out the postural effects upon intestinal function. The position, size, and function of the stomach were more easily ascertainable than those of the cecum, the position of which was changeable in health. Colonic statis was said to allow toxins to pass through its walls. He cited authority for conceiving stasis to be normal when due to the ileocecal valve which retards the terminal ileac current for one hour before passing into the colon. Goldwaithe emphasized the importance of correcting the poise of the body to relieve stasis. Bettmann declared surgery accomplished little for stasis. He quoted Mayo for believing gastroptosis one stage of general visceroptosis, and believed our relation to the affection to-day was the same as it was fifteen years ago. Neurasthenia had been caused by inefficient anchoring of stomach, kidney, and colon. On the other hand, he advised a regulated diet, proper hygiene, abdominal support, and cessation of fussy, meddlesome medicine and surgery. Under the topic adhesions, he said constipation must not be confused with stasis, stasis with ptosis, nor a photographic kink with a pathologic kink. Adhesions were found frequently about the duodenum and gall-bladder, after operations, and especially following drainage of appendical abscess. The symptoms, gas and pain, were aggravated by purgations. Most constipation, he concluded, was curable medically.

Organic Obstruction of the Ileum as a Cause of Gastric Disorder.—Dr. GRAHAM CHAMBERS of Toronto, Canada, said stasis, formerly called constipation, was due to organic disease of every organ in the body (according to Hane), but particularly the ileum. Here it was due to nodular tuberculosis, valveolus, intussusception, also atony, cecal stasis, insufficiency and spasm of the ileocecal valve. He held that the stomach and ileum, both supplied by the vagus and Auerbach's plexus were much alike in motility. Retardation of ileum was of central origin. Excitement caused increased peristalsis. Worry and anxiety caused atony of the stomach and small bowel. Hence ileac stasis was often cured by avacation. Brain work and sedentary habits favored ileac stasis. He compared the ileocecal to the mitral valve, declaring intracecal pressure closed the ileocecal valve during health. He admitted pressure within the ileum was a factor in preventing cecal regurgitation into the ileum. Gastric hypermotility stopped short at the pylorus. Ileac hypermotility stimulated increased cecal activity. The ileum served the purposes of digestion and absorption, the colon that of storage. Autointoxication took place in the ileum affecting the stomach locally as well as reflexly through the resulting mental depression. Cecal stasis might exist without ileac statis. It was due to spasm of the ileocecal valve which, too, affected the stomach. The symptoms, fullness, pain, nausea, and vomiting of appendicitis are those of pylorospasm. He reported a case of organic ileac obstruction associated with increased proximal ileac tonus and gastric residue. Stomach symptoms, he added, were also produced by gastric peptic and duodenal ulcers.

Dr. L. T. LE WALD of New York announced the two views of stasis as he saw them, the one depicted humorously by Dr. G. D. Stewart and the other as the serious regard of Dr. Moynihan. He said he hoped our present attitude would not be changed to disregard kinked ureters and bowels. *X*-ray study should necessarily be complete.

Dr. R. T. MORRIS of New York said that postoperative obstruction was relievable by pituitrin administered intravenously, that hypothyroidism as a cause of intestinal stasis had been omitted, and that too much and too little surgery was done for stasis. He sharply criticised Bettmann's contentions, calling his conclusions dark after bright premises. He added a number of cases of stasis were cured by pretenders by flushing of the bowels. He concluded by asking Dr. Bettmann what Reed said about epilepsy.

Dr. J. T. CASE of Battle Creek continued the discussion by maintaining the condition of the colon with carcinoma to be one of spasticity, not collapse. Dilatation of the right colon was due to retroperistalsis. Instead of speaking of insufficiency of the ileocecal valve in normal persons he advised substituting the words "in symptomless patients."

Dr. T. M. LYNCH of New York remarked that men like Bettmann drove stasis cases to Europe. In Switzerland, where he had studied during the past summer, he had met hosts of Americans, particularly in Switzerland, who said there was no one in America to cure them. He contributed the fact that the ileum is more important than the ileocecal valve in preventing regurgitation from the cecum into the ileum. This, he said, had been indicated by the work of one of the staff. He recommended the reconstruction of the colon to the third position for selected cases. In the cases in which he had performed this operation Auerbach's plexus had been found absent in the part removed. He believed many of the Jackson's membranes and adventitious bands really had no harmful effect upon the bowel. For, he said, there was no such thing as perfect fusion. With increased vascularization bands were formed. When these were cut serious adhesions followed.

Dr. A. L. SORESI of New York spoke of adhesions following operations in dogs. He reported no omental adhesions following instrumental handling in twenty-eight and gauze handling in twenty. The injection of irritating substances, including infectious material, caused marked adhesions. Hands retraction and rough manners were equally potent in producing adhesions.

Dr. BETTMANN thought it quibbling to substitute "symptomless" for "normal" in referring to patients with incompetent ileocecal valves. He added that the results of short circuiting in Cincinnati for epilepsy and other kindred disorders had not been encouraging.

Further Observations upon the Developmental Reconstruction of the Colon, Based upon Surgical Physiology. —Dr. JOHN W. DRAPER of New York read this paper. Bouchard, Metchnikoff, and Coombe had added to our knowledge of autointoxication and intestinal toxemia. The toxins were supposed to arise from hydrolysis of proteids. This change was probably brought about through the action of the anaerobic bacteria of the cecum. The acid reaction of the ileum was supposed to effectually prevent their thriving there. The surgeon could only prevent these toxins once elaborated from entering different segments of the bowel. This amounts to the surgical therapeusis of the colon. Marked acute

and chronic purulent inflammations of the colon were surgical from the beginning. Anatomical variations were greatest in the cecum and the sigmoid. The lymphatics of the colon were scarce and the villi absent except at the apex of the cecum. Both these characteristics suggested that the digestive function of the colon was nil. Given an ill-adopted cecum it might conform to the herbivorous type with stagnation, gas formation, dilatation, attenuation, infection, and destruction of Auerbach's plexus. Barber had shown the important dynamic changes in the duodenum following incomplete and complete obstruction of the extreme caudal ileum and obstruction and inflammation of the cecum. In brief, partial obstruction of the caudal ileum caused dilatation of the duodenum, whereas complete obstruction (effectually interrupting Auerbach's plexus) caused contraction. As analogies, the processes destroying gallbladders and appendices might be mentioned. The difference was we had come to recognize the one, but not the other. Bloodgood had shown that colonic restoration after excision of cancer was more rapid than after removal for other causes. Colitis might vary from the mild catarrhal form to the involvement of the whole wall and properitoneal fat. Dr. McFarland had suggested the hematogenous path of infection for the origin of colitis. The streptococcus was recognized to cause the severest colitis encountered, although the colon organism had been obtained from a lymph gland of one of their cases. Adhesions were found exaggerated in mild infections and absent in severe infections. To illustrate these observations many cases were reported. One indication for surgery was hemorrhaghic colitis embracing acute streptococcic embolic colitis, chronic torpid ulcerous colitis, and acute diphtheroid colitis. Lynch and Draper believed the function of ileocecal valve possibly overestimated and the relative neuromuscular power of the ileum unappreciated. In the ureter it had been shown that normal peristalsis was far more protective than the ureterovesical valve. Ileostomy was indicated in multiple polyposis and hemorrhagic colitis. In the severest cases developmental reconstruction had been performed with 23.1 per cent. mortality in thirteen cases of whom 46.2 per cent. were cured and 7.7 not improved. His conclusions were that the extent of the infection should be determined, that ileostomy should be done for one case and colostomy for another. Many segmental infections relapsed and gave rise to strictures. Infection originally simple always became a mixed infection as in the lungs. Heredity and the upright posture played important parts in pathology of the colon.

Diagnosis of Colon Cancer.—Dr. Joseph Burke of Buffalo said in loss of weight carcinoma should be suspected. There might be abdominal mass with or without marked peristaltic pain. Pain about the lesion frequently radiated into the back and might or might not be due to local peritonitis. Blood appeared in flakes or in large amount. One never got gray stools in carcinoma of the colon. Diagnosis of cancer of the colon was difficult. Appendical and ileocecal tuberculosis should be excluded. Had seen three cases of cecal cancer with constant elevation of the temperature. In cancer temperature was considered frequent. One got a positive diazo reaction and tubercle bacilli in the stools in cecal tuberculosis. He reported a case of hepatic flexure carcinoma with diarrhea, loss in weight and strength, and tumor in the right hypochondrium which could be held fixed during respiration. In cancer of the greater curvature of the stomach he got coffee-ground vomitus, Boas-Oppler bacilli and absence HCl. Some cases of colon cancer had ruptured into the stomach. Cancer of the sigmoid gave a negative roentgenogram. Sigmoidal growth gave construction and was not palpable. Diverticulitis occurred in well-nourished individuals of sounds musculature and was accompanied by high temperature and leucocytosis. The treatment comprised an early diagnosis of the colonic growth and proper x-ray study.

Dr. Martin B. Tinker of Ithaca, in discussion, said that surgeons and internists were at odds in the treatment of intestinal stasis. He had observed the work of different progressive clinics; had seen one colectomy and several ileosigmoidostomies performed. Most surgeons would desire medical treatment as long as feasible. Those patients who were not relieved should be given an opportunity for surgical relief if there were hope. He believed the trend was away from complete colectomy. Ileosigmoidostomy was discarded by most of the surgeons of the country. He recalled the A. M. A. report of W. T. Mayo's partial colectomy. Draper deserved considerable credit for showing us why these cases should be so treated. All knew how many cases of polyposis degenerated malignantly and terminated fatally. Lynch and Draper had proposed a simple procedure, ileostomy, which some of us would be disposed to adopt.

Dr. T. M. Lynch pleaded for early diagnosis of cancer. He declared he had seen 400-500 cases. Amebic dysentery and colitis should be differentiated. The x-ray he did not consider of great value. One might have a carcinoma with but few symptoms. It might occur at about the thirtieth year. The palpation of a mass and the discharge of bloody mucus, especially if without apparent cause, were very important. Differential diagnosis between diverticulitis and carcinoma was often impossible. Indigestion was an early symptom and constipation a constant sign. The difficulty of emptying the bowel in cancer by enemas was suspicious. He finished his discussion by showing lantern slides of the colon, two of which, depicting the vascular and sympathetic relations of the colon, were particularly noteworthy.

Dr. A. L. Soresi of New York advocated an oblique anastomosis in contradistinction to a side-to-side or end-to-end, chiefly because of the conservation of the blood supply. This he demonstrated by slides and specimens.

Early Recognition of Cancer of the Stomach. — Dr. Julius Friedenwald of Buffalo declared early recognition important, for without this only relief was possible. Of 1,000 cases of gastric cancer indigestion appeared in 23.2 per cent., ulcer symptoms in 7.2 per cent., or 73 cases. The onset was sudden frequently. Important symptoms or signs were anorexia, vomiting, hematemesis, pain, dysphagia, tumor, dilatation of stomach, ascites, and edema, x-ray and serodiagnosis by the Abderhalden method. Anorexia occurred in 89 per cent., slight in 23 cases early; vomiting in 89 per cent., in 67 per cent. unassociated with eating; pain in 93.1 per cent., in 56 per cent. over entire abdomen, in 22 per cent. at the umbilicus, in 1 per cent. in the chest, in 84 per cent. as an early sign, hemorrhage in 22 per cent., in 88 per cent. multiple, in 10 per cent. single, in 21 per cent. early, in 79 per cent. late; melena in 18 per cent., in 14 per cent. early and 86 late; occult blood in 92 per cent., constant and early; dysphagia in 78 per cent., an early sign; loss of flesh in 98 per cent., from 5 to 78 pounds; palpable tumor, usually late, 30 per cent. in 6 months; dilatation of the stomach in 47 per cent.; ascites in 4 per cent.; edema in 10 per cent., combined in 21 per cent.; x-ray showed early contraction of stomach, bulging behind the pylorus, filling defect—a useful and important aid, but doubtful in early cases; gastric secretion in 89 per cent., free HCl absent, but it is often absent in other than cancer cases; in 82 per cent. lactic acid; in 79 per cent. Boas-Oppler bacilli, early in 74 per cent.; Wolff-Yunghaus test + in 44 per cent., Abderhalden reaction + in 60 per cent., Kelling's serum test + in 90 per cent. Simon found it in no way specific for cancer. The treatment was surgical, in doubtful cases medical, and if not cleared up medically surgical, especially with loss of weight, no HCl, and occult blood in the stool.

What Stomach Symptoms Justify Surgical Intervention.—Dr. Martin B. Tinker of Ithaca said nonsurgical conditions as eye-strain, heart lesions, gastric crises, cirrhosis, abdominal aneurysms, and chronic nervous disorders should be eliminated. As symptoms of cancer or of ulcer he considered pain which when frequent and persistent was an indication of serious trouble; hunger pain, gas, and distress, vomiting, especially of blood; periodicity, which occurred in gallbladder as well as in ulcer; downward course in health, tenderness localized over lesion, visible peristalsis, and gastric analysis, although neither positive nor negative evidence of carcinoma. Blood was found in 49 per cent. by Mayo, 43 per cent. by Peck, 50 per cent. by Tinker, and 40 per cent. by Brewer and Cole. Increased acidity, he said, denoted ulcer. Blood in vomitus or feces, he thought, was most indicative of carcinoma. The value of x-ray he held to have been pertinently represented in Brewer and Cole's 23 cases, 20 of which had been correctly interpreted by the rays. Osler and McCrea advised studying every case from the standpoint of a possible ulcer or cancer.

Dr. A. L. Soresi of New York discussed the comparative advantages of gastroenterostomy, pylorectomy, and gastroectomy.

Dr. L. T. Le Wald of New York reported eight cases of syphilis of the stomach from St. Luke's Hospital during the past two years. Dr. Meyer had also reported a case, in which he had performed a pylorectomy. The histories were doubtful and Wassermann positive. He illustrated by slides the dumbbelled shaped stomach, which must be differentiated from tuberculosis.

Dr. R. T. Morris of New York emphasized the importance of differentiating eye-strain.

Dr. H. L. Elsner of Syracuse pleaded for education of the public similar to the campaign against tuberculosis. He emphasized resistance in epigastrium as a sign of cancer.

Dr. S. T. Pilcher of Brooklyn pointed out that the arteriosclerosis of senility retarded metastasis.

Dr. C. G. Stockton of Buffalo said adenocarcinoma started in submucosa and developed before it could be found.

Dr. Parker Syms of New York recalled from Mayo's reports 70 per cent. of cancers having had a previous ulcer history and favored removal of ulcer-bearing area in operating for ulcer.

Dr. Levy of Syracuse believed cases should get proper medical treatment before being turned over to the surgeon.

Dr. A. Jones of Buffalo advised the use of the Einhorn bucket to determine potency or stenosis of pylorus.

Dr. Tinker concluded the discussion by recalling that Osler had mentioned eye-strain as a cause of stomach symptoms fifteen years ago.

The Rôle of the Superior Mesenteric Vessels in Abdominal Disease.—Dr. Josiah N. Hall read this paper. He outlined the anomalies of the mesenteric vessels. Arteriosclerosis of the superior mesenteric was a cause of angina abdominis and should be considered as well as the gross stomach lesions. Veins, also, might be sclerosed. He said arterial embolism was three times as frequent as thrombosis. Thrombophlebitis occurred in hepatic cirrhosis, syphilis, and food poisoning. He spoke briefly of dilatation of the stomach and its association with the supposed pressure over the duodenum by the mesenteric vessels.

SECTION ON MEDICINE.

Tuesday, April 27—First Day.

Dr. G. Reese Satterlee of New York, Chairman.

Mouth Infection as a Source of Systemic Disease.—Dr. S. Marx of Minneapolis, Minn., read this paper. The systematic work of the Medical Clinic of the University of Minnesota in this field began two years ago. All patients had a preliminary examination of the mouth to determine gross evidences of alveolar or dental infection. All patients giving such evidence were referred for study and relief of the mouth conditions to the dental service. In recent years renewed interest had been aroused by the discovery of methods which revealed the presence of alveolar abscesses with an ease and directness previously impossible. The study of focal infections in the mouth was only a part of that of focal infections in general. Experience had shown that the principal sites in which chronic foci might be found were as follows: (1) the secondary nasal cavities, *e.g.* ethmoid, sphenoid, frontal, and maxillary; (2) the middle ear and mastoid antrum; (3) the tonsils; (4) the alveolar processes, including all forms of dental and paradental infections; (5) the genitourinary tract, chiefly the prostate and seminal vesicles in the male, and uterine adnexa in the female; (6) gastrointestinal tract, including the gall-bladder, and the appendix. The relation of the tonsils to the dissemination of septic infection had been increasingly recognized during the past decade and the work of Poynton and Payne, as well as others, was well known. It was, however, to the fourth group given above that they were paying particular attention at the present moment. Infection of this region might be roughly divided into two groups: (1) infections about the teeth, giving the so-called pyorrhea pocket, and (2) abscesses and necrosis in the jaw, usually at the tips of the roots, with or without sinus formation. The importance of these two groups appeared to be almost equal. The recent finding of endamebas by Smith and Barrett in pyorrhea, confirmed by other writers, gave a new aspect to the study. The discovery in emetine of a specific remedy against these parasites gave an opportunity to determine promptly whether or not the endameba was pathogenic and whether distant effects could be produced by it. The studies in their clinics and elsewhere did not appear to him to be conclusive as yet, and much time would be required before definite conclusions could be reached. Dr. White said that he had reviewed the experience in their Medical Clinic from October 1, 1913, to January 1, 1915, with the purpose of showing the class of cases in which dental and paradental infections were found with evident relationship to systemic disease. The admissions to the medical service for the period covered were 565. Of these 55, or 9.7 per cent. of the entire admissions had pyorrhea, alveolar abscesses, or both, and had been included as instances of mouth sepsis, with evident or probable relationship to systemic disease. These cases were tabulated and charts were shown. Table IV. was a summary of Tables I., II., and III. as follows:

	Tonsillitis	Pyorrhea	Alveolar Abscess	Chronic Arthritis	Acute Rheumatism	Endocarditis	Nephritis	Arteriosclerosis	Septic Ulcer	Anemia, Secondary Type	Anemia, Pernicious Type	Vaccine
Total, 55 cases	15	35	40	16	7	25	13	10	4	22	5	12
Tonsillitis	..	3	7	6	3	8	2	2	1	6	0	.
Pyorrhea	..	12	14	10	4	15	11	7	3	18	3	..
Alveolar abscess.....	..	15	14	12	6	20	7	6	2	14	3	..
Tonsillitis, pyorrhea, and alveolar abscess.	..	5	5	3	1	2	1	1	..	3	..	.

As shown in the 55 cases included in this study, tonsillitis occurred in 15, or 27.3 per cent. In 3 it occurred with pyorrhea, in 7 with alveolar abscess, and in 5 with both. It showed that from this tabulation of 55 cases, as many more cases with mouth infection in their wards had been excluded because of a lack of any definite relationship to the clincal condition. Two conditions demanded that all foci should not be eradicated at once. The first was that in cases vaccines or bacterins were needed, if all foci had been eradicated and attempts at cultivation of bacteria had failed or gone awry, material for culture could not longer be secured. Secondly, the measures necessary for elimination of the infection frequently stirred up and increased the infection at the time and there was considerable danger, particularly in heavily infected individuals, of opening up many channels of infection, of severe local reactions, sometimes with necrosis, and frequently of aggravating a multiple joint infection, or even an endocardial or myocardial involvement. These dangers were real.

The Relation of Focal Infection to Ulcer of the Stomach, Cholecystitis, and Appendicitis.—Dr. Edward C. Rosenow of Chicago, presented this communication. He said that he wished to show by means of the lantern slides that appendicitis, ulcer of the stomach, and cholecystitis, as well as rheumatic arthritis, were due in many instances to streptococci because they were so commonly found in the lesions and because they produced the respective diseases in animals when injected intravenously. Similar results had been obtained with streptococci isolated from various foci of infection at the time of the acute attack as during exacerbations, but usually not later. This fact suggested strongly that the tonsils, pyorrheal pockets, and other foci of infection, not only afforded the entrance way for the bacteria, but the very conditions which he had shown in his transmutation work to be favorable for the acquirement of new properties of streptococci. Thus streptococci from appendicitis, on isolation, produced infection in the appendix in 41 out of 59, and after cultivation in only 3 out of 22 rabbits; streptococci from ulcer of the stomach, on isolation, produced ulcer in 50 out of 79, and after cultivation in no instance in 17 animals; from cholecystitis, on isolation, in 22 out of 27, and after cultivation in only one out of 12 animals; and from rheumatic arthritis, on isolation, arthritis developed in 47, endocarditis in 33, myocarditis in 31 and pericarditis in 19, out of a total of 71 animals, and after cultivation this affinity had largely disappeared as shown in 14 animals injected. The strains from erythema nodosum produced similar results. The lesions in other organs were either entirely

absent or slight in a large percentage of the animals. Among other things he emphasized the fact that when streptococci attained a certain grade of virulence, irrespective of their original source, they were prone to localize in the mucous membrane of the stomach of animals, producing ulcers which resembled those in man in that they tended to persist and perforate. Again in focus infection in cases of rheumatism, there were present conditions favorable to the development and growth of streptococci of that particular type. As a result there was a marked transmutation within the streptococcus or staphylococcus group. There were varying degrees of virulence. Dr. Rosenow looked upon the focus of infection not only as an *infection atrium*, but as a breeding spot.

Pyorrhea Alveolaris, and Some Modern Discoveries Regarding Its Causes and Treatment.—Dr. FRANCIS E. STEWART of Philadelphia read this paper. He said that pyorrhea alveolaris or Riggs' disease was for many years a perennial subject of discussion in dental societies before it attracted the attention of the medical profession to any extent. Its importance as an etiological factor of many systemic diseases had not been appreciated until recent years. It was well known to-day that a septic mouth might be the cause of affections of the eye, ear, throat, bronchial tubes, heart, liver, kidneys and other organs of the body. According to Osler, pyorrhea alveolaris was almost constantly present after middle life. Head states his experience indicated that it started between the ages of eight and ten years, and became perceptible between the ages of forty and fifty. Haskin said that cases were found in countless number, in the rich as well as in the poor. The recent discoveries in regard to the etiology and treatment of so-called Riggs' disease were therefore of sufficient importance to warrant their earnest consideration by the medical as well as the dental profession. Pyorrhea alveolaris was not a modern disease, for Galen (131 A.D.) was supposed to have referred to this condition when he said, "the lack of nutrition makes the teeth weak and brittle, and excess of nutrition excites a kind of inflammation similar to that of the softer parts." It was said that a study of the skulls in the Hunterian Museum, which included 5,000 specimens, showed that it was a disease of the early Egyptians. It seemed to have prevailed during the decadence of the Roman Empire and to have been universal among civilized nations from very early times. Ambroise Paré (1550) also described this condition. Many authorities laid stress upon the danger of systemic infection from septic conditions of the oral cavity, and considered the disease sufficiently widespread and injurious to warn the profession in regard to it as a serious menace to public health. Pyorrhea alveolaris was a mixed infection, protozoa and bacteria both being present. The use of ipecac or emetine hydrochloride would destroy the protozoa, as demonstrated by Barrett and Smith, and confirmed by Bass and Johns. The bacterial action must then be combatted. Five or six principal types of bacteria took part in the infection. The infection might be limited to the tissues of the mouth, or there might be one or more foci elsewhere, resulting from the extension of the infection. The object of treating pyorrhea alveolaris with bacterial vaccines was to stimulate the body cells to form substances antagonistic to the invading bacteria. For that purpose, either an autogenous vaccine might be employed containing the various germs found in the pockets of infection, or a mixed polyvalent stock vaccine might be used.

Finally, Dr. Stewart called attention to the fact that pyorrhea alveolaris was a name of a condition rather than a disease, a condition in which local and systemic factors cooperated in reducing the vitality of the patient, and that this reduced vitality enabled the organisms taking part in the condition to grow and reproduce at the expense of the patient's tissues. Also the tissues infected were not limited to the tissues of the mouth. Focal infections might exist in any organ of the body as a result of pyorrhea alveolaris, and the existence of such focal infection might be sufficient in its influence to greatly retard the cure of the patient's condition. Therefore, in treating pyorrhea alveolaris it was necessary not only to use amebicides, bactericides, and operative methods for the purpose of destroying the infecting organisms in the mouth, but also to employ systemic treatment to meet systemic conditions. The systemic treatment should include not only the use of ipecac or emetine hydrochloride and bacterial vaccines, but also accessory and concomitant measures, as indicated to meet the conditions existing in each individual patient.

Lantern Slides Showing the Proper Method of Brushing the Gums.—Dr. JOSEPH HEAD of Philadelphia gave this demonstration. He said that hardly a man knew how to clean the back teeth, and therefore the back teeth were seldom if ever cleaned. Bacterial masses were allowed to thrive there. They talked about eliminating mouth infection, but they did not give it the unwearying study they did to their beautiful course in physical diagnosis. About five years ago Dr. Head said that he woke up to the fact that there should be a more scientific method of cleaning the teeth. Therefore, he got a skull and made some careful studies, and evolved a method which he showed by means of moving pictures. Really the only instrument in the world for properly cleansing the teeth was floss silk. If the dental floss silk was used twice a day, and the teeth properly brushed, as he himself showed how to do, such a condition as pyorrhea alveolaris could always be cured. They should have, too, a properly constructed brush with bristles only one-quarter of an inch long.

Dr. JOHN OPPIE MCCALL of Buffalo said that the papers on pyorrhea alveolaris seemed to show that the disease was of parasitic origin, with excessive numbers of bacteria present. But there were in his opinion other factors to be considered. In Buffalo they had not succeeded with these injections of emetine and other substances—they had not gotten the results that people away from Buffalo had claimed for them. Such results as were claimed could not be obtained here. But they did obtain decided improvement in this disease by the employment of various agents. There was present in many instances calculi, or calcium deposits on the teeth which produced a mechanical irritation. Such calculi or deposits must be removed by one of the various forms of steel instruments or solvents. Again in bridge-work and crown work the condition of the teeth favored the inception of a local infection about the roots.

MEDICAL ASPECTS OF CANCER.*

By L. Duncan Bulkley, A.M., M.D.,

New York.

Senior Physician to the New York Skin and Cancer Hospital, etc.

In his recent president's address before the American Surgical Association, Dr. William J. Mayo spoke in regard to the internal causation of cancer in a manner which should attract serious attention. Few have had a wider acquaintance with the surgical aspects of the disease than he, and few others know better than he how relatively impotent surgical procedures are to stay the steadily increasing mortality from cancer, which now claims about 90 per cent. of those whom it once attacks.

As a text for what I have to say, I want to quote a few of his words, as they confirm so strongly the views I have held and by which I have practised for thirty years and more, with results which I have seldom, if ever, had cause to regret.

Speaking of the prophylaxis of cancer, mainly from its surgical aspects in regard to early operation, Dr. Mayo says: "Cancer of the stomach forms nearly one-third of all cancers of the human body. So far as I know this is not true of the lower animals, nor of uncivilized man. . . . Is it not possible, therefore, that there is something in the habits of civilized man, in the cooking or other preparation of his food, which acts to produce the precancerous condition? . . . Within the last 100 years four times as much meat is taken as before that time. If flesh foods are not fully broken up, decomposition results and active poisons are thrown into an organ not intended for their reception and which has not had time to adapt itself to the new function." In conclusion he says: "Where cancer in the human is frequent, a close study of the habits of civilized man as contrasted with primitive races and lower animals, where similar lesions are conspicuously rare, may be of value, and finally the prophylaxis of cancer depends, first, on a change in those cancer-producing habits, and second, on the early removal of all precancerous lesions and sources of chronic irritation."

I shall hope to show you that cancer is indeed a disease of modern civilization, like tuberculosis, although of quite a different nature, and that the increase in its prevalence and mortality has closely followed the habits of man, in regard to diet and mode of life, as influenced by so-called civilization. We shall see that as the death rate of tuberculosis has diminished, that of cancer has steadily increased, the one under improved nutrition, the other under excessive or erroneous nutrition.

*Address before the Rhode Island Medical Society, March 4, 1915.

It is strange that the medical profession has been so slow in accepting, or unwilling to accept and act upon the suggestions along this line which have been thrown out from time to time, for very many years, by surgeons of prominence who were well acquainted with cancer, and who felt their inability to cope with this distressing and fatal disease. And yet innumerable, earnest, faithful, and intelligent research workers have expended any amount of time and labor, countless animal lives have been sacrificed, and vast sums of money have been spent in searching for the cause of malignant disease, with little if any but negative results; from the standpoint of laboratory investigations thus far a satisfactory answer as to the problem of cancer seems as distant as ever, with no practical suggestions in regard to the prevention and cure of the malady, except by local means, including surgery, *x*-ray, radium, etc.

From the surgical aspect the problem does not seem much brighter, as we shall see later. All honor to the surgeons who have so earnestly and valiantly striven to cure the disease by these means, but alas, their efforts have proved unavailing to check to any degree the constant rise in the general death rate from cancer, as shown by the mortality tables from many lands; and this is because the effort has not been along the right lines, as I shall hope to show.

I am well aware of the improvement in surgical statistics which has been reported in regard to cancer in certain localities during the last few years, and of the importance of very early operations, if good results are to be obtained; but I hope also to show that the same pertains to the dietetic and medical treatment of the disease. While operative procedures may remove the tumor, and with it the source of toxic material generated in the same, they do not in any way affect the primeval or basic cause of the trouble; whereas, if exactly the right measures are employed to reach the fundamental source of the difficulty, not only will the original new formation disappear but there will be little or no tendency to its recurrence. What these lines of causation are will appear later.

Dietetic and medical treatment of cancer, in the fullest sense, have never been given a fair and completely intelligent trial, on a scale large enough to produce general conviction in regard to their value and to lead to their general adoption. With a rather extended experience during the last forty years, I have rarely if ever found a patient with cancer who has received adequate and continuous medical care and treatment before operation, with a view of discovering and rectifying the cause of the morbid growth. Too often when a cancer is suspected or discovered it is taken as a foregone conclusion that the malady is hopeless, except as the *results of the disease*, that is the new growth, may

be removed by the knife, *x*-ray, radium, caustics, etc.

Also after a surgical operation, as far as my observation goes, the patients are invariably left entirely to their own resources, with the hope, alas, too often futile, that the tumor will not regrow, but with no attempt to so guide the life that there shall no be the same tendency to a recurrent malignant new formation as before. Against this latter course I also raise my earnest protest.

That you may know that Dr. Mayo is not alone in his impressions that there is "something in the habits of civilized man . . . which acts to produce the precancerous condition," I must very briefly refer to some of the leading surgeons of the past who, from time to time, with more or less force, have claimed that the disease is constitutional, and that it depends largely on diet and mode of life: later I shall hope to present sound grounds for such belief.

One hundred years ago Lambe wrote clearly in regard to the causation of cancer from luxurious living, and adduced strong proof to show the effect of diet in curing certain cases of undoubted cancer of the breast and uterus.

Abernethy, shortly after, wrote pointedly regarding the constitutional origin of tumors, endorsing Lambe's dietetic treatment of cancer and presenting several reasons why it should be fairly tried.

Walshe in his classical work on cancer, says, "It would in theory appear that the removal of a tumor cannot in itself cure the disease, as the local formation is but a symptom of the general vice of the economy," and he alludes more or less to the effect of diet on the disease.

The late Willard Parker, one of New York's great surgeons, in a study of 397 cases of cancer of the breast, observed from 1830 to 1880, wrote very strongly in regard to the constitutional relations of cancer. In considering its etiology he places first "luxurious living and particularly excess in animal food." He says, "Cancer is to a great degree one of the final results of a long-continued course of error in diet, and a strict dietetic regimen is, therefore, the chief factor in the treatment, preventative and curative." He further says, "In regard to the effect of abstemiousness on cancer I can speak with great positiveness, that vegetable, or at least a very bland diet, does check the progress of the disease, and in some cases now under treatment has been attended by an alleviation of symptoms; and in a few instances even by a recession of the growth."

Sir Astley Cooper is quoted by Dr. Parker in some strong language, as follows: "The cause of this disease is supposed to be some accidental blow or the pressure of a part of the dress; but although the blow may produce a swelling on the bosom, yet that swelling will not be of a schirrous nature unless some defective state of the constitution disposes to malignant action. If the constitution be good the effects of the blow are speedily dissipated: but if the constitution be faulty, the swelling grows into a formidable disease." Later we shall see what some of these constitutional conditions are which induce certain cells of the body to take on malignant action.

Sir James Paget, that prince of surgeons and pathologists, comes out very strongly for the constitutional origin of cancer when he says twice in his Lectures on Surgical Pathology that cancers are "local manifestations of certain specific morbid states of the blood"; and again, he says, "I believe it to be constitutional, in the sense of having its origin and chief support in the blood . . . "the existence of the morbid material in the blood, whether in the rudimental or effective state, constitutes the general predisposition to cancer."

Benecke, in 1875, elaborated a diet highly beneficial in cancer, which was endorsed by Esmarch and Oldehop.

If time permitted I could give any amount of further corroborative evidence, in the way of scattered remarks and allusions, like those of Dr. Mayo, expressing the conviction of many others, that cancer is not a purely local affection, but is only the result of some previous systemic disturbance, which we now recognize as metabolic.

But these many fugitive observations have never attracted the attention they deserve, and it would sometimes seem as if they were deliberately ignored, and that scientists and practitioners had combined to recognize only the local nature and treatment of cancer. The truth is that very little serious effort has ever been made to assemble all the evidence of the constitutional nature of the disease, and by synthesis and deduction to establish a basis for the recognition and treatment of the constitutional elements of cancer. While it has been quite impossible to gather all the proof that could be desired, I shall hope to give enough to establish the correctness of the basis of the thesis which I have long held.

Cancer is more or less widely diffused over the whole globe, but in singularly different degrees in various sections, and time will permit of only the briefest statement of the same, which can be verified and expanded from the remarkable recent works of Williams and Wolff.

Thus, in England cancer mortality is very high, and during the past 40 or 50 years it has increased four or five fold, while the population has only a little more than doubled. Switzerland is credited with having the highest death rate from cancer of any country, it having augmented from 114 per 100,000 living in 1889 to 132 in 1898. Denmark stands next with 130 per 100,000 living in 1900, and France has a high cancer mortality, with a constantly increasing death rate. In Paris it has increased from 84 per 100,000 living in 1865 to 120 in 1900. In Holland, the death rate from 1867-1879 was 49 per 100,000, and 101 in 1905.

The United States shows a lower death rate from cancer than the countries mentioned, namely 78.9 per 100,000 living in the registration area in 1913; but it had increased from 63 in 1900, over 25 per cent, while deaths from tuberculosis had fallen a little over 25 per cent: in 1913 there were over 50,000 deaths from cancer in the United States. In a recent study regarding New York, Boston, Pittsburgh, Baltimore, Chicago, Philadelphia, and St. Louis, it was found that there had been an increase of almost 8 per cent of deaths from cancer in their combined population in 1913, as compared with the average of the five years preceding.

I am quite aware that some have claimed that the increase of deaths from cancer is only apparent, and not real, and is accounted for by a greater longevity into the cancer age, by more accurate diagnosis, and by greater exactness in recording deaths. But these points have been carefully and satisfactorily refuted by Williams, and surely the increase of 8 per cent in these seven cities could not be thus accounted for. In New York City, ac-

cording to the Weekly Bulletins of the Board of Health, there were 2173 deaths from cancer in the six months from May to November, 1914, or almost twelve deaths daily from malignant disease.

While cancer is steadily increasing everywhere, under the influence of modern civilization, there are certain sections where the mortality is much lower than has been mentioned.

Thus Italy has a low but increasing mortality, it having risen from 20 per 100,000 living in 1880 to 58 in 1905. Hungary had a cancer death rate of 26 in 1897 and 39 in 1903; in the county of Kerry, Ireland, the cancer death rate was 26 and in the province of Dalmatia 16 per 100,000 living population.

In some regions, however, cancer is very rare and in others almost unknown. In Africa all observers agree that the disease is exceedingly rare, as also among those in the interior of China and India; in Brazil it is seldom seen, while several testify that in many of the islands of the sea it is practically unknown.

During a rather extensive trip through the Far East I was unable to see or hear of any cancer, although I met a large number of medical men, and made diligent inquiry regarding the same. I visited very many civil, military, and mission hospitals, with a total of many thousands of patients, and ministering to many millions of population: in Japan, Korea, China, the Philippines, India, Siam, and Egypt, I met the same response, that cancer was very rarely seen among the natives.

Now there must be some reason for this unequal distribution of cancer. Laboratory researches have not helped us in discovering it, except that they have done much to clear the way for a proper understanding of the real nature and cause of cancer, though the evidence furnished is largely of a negative character. In order to appreciate fully the basis on which our thesis rests, it will be well to state very briefly the accepted facts in regard to cancer.

1. Cancer is but a deviation from the normal life and action of certain of the ordinary cells of the body.

2. It is possible that the diseased action may begin first in what is known as "embryonic rests," or pre-natal, wrongly placed tissue elements.

3. Cancer is *not* wholly of traumatic origin.

4. It is *not* caused by a microorganism, or parasite.

5. Cancer is *not* contagious.

6. Cancer is *not* hereditary in any appreciable degree.

7. Occupation has *not* any great influence on the occurrence of cancer.

8. Cancer is *not* altogether a disease of old age.

9. It does *not* especially belong to or affect any particular sex, race, or class of persons.

10. Cancer is *not* confined to any location or section of the earth.

11. *No* single cause of cancer has yet been demonstrated, nor is it likely that this will ever be the case, as the experimental and other investigations have covered almost every possible line of research, with only *negative* results.

But there must be some cause, or reason, why cancer is thus unevenly distributed and why it is so steadily increasing almost everywhere; why it is so exceedingly prevalent in some localities and among certain peoples, and again so rare or even absent among others; for we have seen that aborigines are not affected, while others, in proportion as they have been affected by so-called civilization are correspondingly affected. Wolff has shown in a remarkable table, that while cancer in the native Australians has remained about stationary, it has increased among the English residents in cities *seven fold*, and another writer remarks that while the native Australians are practically free from the disease, when they mingle with foreigners as servants and employees and adopt their diet and customs it occurs more frequently among them. The same has been observed among native Africans and those in India and elsewhere.

Analyzing the various data obtained, we find that cancer has increased in proportion to the consumption of the three articles, meat, coffee and tea, and alcohol.

In England, where the consumption of meat has doubled during the past fifty years and recently was 130 pounds per capita yearly, cancer mortality has increased *four fold*. In Italy, where the consumption of meat is the least of any of the European countries, cancer is least frequent, and in the county of Kerry, Ireland, where meat is seldom eaten, the death rate from cancer is not one-third that in England. The same comparison may be made between a number of other countries, did time permit. The United States in 1909 consumed much more meat than England, namely 172 pounds per capita, and, as already stated, cancer has increased over 25 per cent. since 1900.

Alcohol must also be accredited with a portion of the increase of cancer in both these countries, as it is well known that the disease presents a far greater augmentation in those occupations where alcoholic drinks are indulged in, as in bartenders, printers, and others.

Coffee has been shown to have its largest per capita consumption in Holland, where the cancer death rate is among the highest, while Hungary is the smallest consumer of coffee, and the cancer mortality there is among the lowest, namely 39 per 100,000 living. The people of the United States consume one-third of all the coffee produced, more than Germany, Austria, Hungary, France, and the United Kingdom combined. England and her colonies, where cancer is steadily increasing, consume one-half of the world's output of tea.

Williams has given some interesting and important data regarding the effect of prosperity and wealth, leading to self-indulgence and indolence, in the augmentation of cancer mortality, which time does not permit our long dwelling upon. He shows clearly that as these elements of modern civilization have developed, cancer has surely increased, and he gives striking illustrations of the same. In England it was found in one decennium that cancer mortality was more than twice as great among well-to-do men, having no specific occupation, as among occupied males in general, the ratio being 96 to 44.

Nerve conditions have also been found by many to be an important element in the production of cancer, and the very great nervous strain accompanying modern civilization must be reckoned among its causative factors, possibly through its effect on metabolism.

To understand how these various elements mentioned, and probably others, have an influence in the genesis of cancer we must briefly consider the physiology of nutrition and the metabolism of cancer as far as it has been ascertained.

All recognize, of course, that the body nutrition, in health and disease, depends upon the nutritive elements taken into the system, as proteids, carbohydrates, and fats, with oxygen inhaled and water imbibed. We know, of course, that there is a certain equilibrium to be maintained in regard to its various component parts, and that over-indulgence in certain articles can without doubt produce disease as, for instance, acute or chronic gout from free indulgence in Port and Madeira wine. Just where the fault lies, and why, after a certain time the system rebels and refuses to properly metabolize and remove waste products, or why the latter exert such a baneful influence on different portions of the economy, and give rise to various inflammations and misgrowths, is hard to tell, and must be the subject of future study, but the fact no thinking man can doubt. Later we shall hope to throw some little light upon it.

The metabolism of cancer has been the subject of considerable research, and there have been many reports in this direction which can be but briefly alluded to here; unfortunately, however, most of these investigations have been made upon advanced cases, where the system has been already depressed by the poisonous toxins produced in the already well-developed cancer mass, or where the disease process has already involved important viscera and interfered with their proper action. What we need is careful metabolic studies on precancerous states of relative health, also in very early cancer, and likewise after surgical operations, when the local manifestations of the disease have been removed: only thus can we rightly learn the true errors of metabolism which lead up to cancer.

But enough has been developed to show that the cancerous person manifests grave aberrations from the normal state, other than the local tumor.

The *blood* exhibits great changes in cancer, especially toward the end of the disease. The haemoglobin content tends to constantly fall, and the red cells to diminish, and to exhibit various phases of degeneration. The white cells increase, and the proportion of their varieties changes greatly. Unfortunately the plasma has not been much studied, and yet the condition of this fluid must be of the utmost importance, as from it are derived not only the solid constituents of the blood but also those of the entire system. It also holds in solution the phosphates, carbonates, sulphates, and chlorides, the latter often varying greatly and being chiefly responsible for the isotonic relation of cells and serum. In cancerous cachexia a diminution of carbonic acid, a constantly diminished alkalinity, and an increase of acid principles of the blood have been fully demonstrated, pointing in all probability to an acid intoxication. It seems that the toxic secretion from a cancerous mass itself has a distinctly injurious action on the blood, for after the complete removal of a cancerous mass there is often found an increase of haemoglobin, as I have witnessed, and a high leucocytosis has disappeared after the removal of schirrus of the breast, only to return again with the recurrence of the tumor.

The *urine* in cancer has also been much studied, and is rarely if ever found to be that of health, although it cannot be said that any definite and specific changes have been established which are pathognomonic of the disease: the urinary excretion will constantly be found to be extremely deficient, both as to its quantity and its total solid elimination. In one very interesting case of primary cancer of the breast, in a stout, flabby lady, near 55, in private practice, the total quantity of urine, meased daily for weeks, is always very far below the normal amount, and in spite of active medication it seems almost impossible to raise the total daily solids excreted in the urine, to much more than one-half of that called for by the weight of the patient. This I have observed in very many cases.

In regard to the changes which have been reported in the urine of cancer patients, many observers agrée that there is a disturbance of proteid metabolism, and dependent upon this many deviations from normal are found in the urine. The urea is invariably diminished, often very greatly, as I have verified time and again in many cases. The nitrogen partition is greatly disturbed, with increase in colloid nitrogen to more than double the normal amount, and an increased elimination of xanthin, oxyproteic acid, and urinary ammonia; oxyproteic acids are reported by Blumenthal as increased even in very early cancer, and independently of the size of the tumor and degree of cachexia, seemingly showing them to have some specificity for cancer, because they have not been found in other forms of malignancy.

Notable changes have also been recorded concerning the sulphur elements in the urine, with a great increase in neutral (unoxidized) sulphur, and a considerable excess of sulpho-cyanic acid, together with an increase in sulphates and indican, showing the results of intestinal fermentation of protein elements, which I have also constantly observed. There have been likewise other changes reported, which time forbids our considering.

The *saliva* is an important element in the digestion of carbohydrates, and consequently in metabolism and the genesis of cancer; but, unfortunately, I have not been able to find any investigations relating to its condition in this disease. But in very many tests which I have made in cancer patients it is commonly found acid, often strongly so; in my hospital cases I have it tested before and after each meal, and watch with considerable interest its change to alkaline under efficient treatment, which includes prolonged mastication.

The *internal secretions* have also been the subject of much research and speculation of late years, in regard to their influence on metabolism and the life processes of the economy, and some studies have been made concerning their connection with cancer, which cannot now be long dwelt upon. But there seems to be little doubt but that the secretions of the ductless glands in common have much to do with regulating the metabolism of the body cells. We know, for instance, that disease of the pituitary body produces bone disorder, resulting in gigantism, that thyroid derangement results in myxedema, and that disease of the suprarenal capsules gives rise to Addison's disease, or bronzed skin. May we not rightly argue that derangement in one or more of these has something to do with the cellular changes which we call cancer? The favorable results which have attended the administration of thyroid, which I have myself often witnessed, as also a combination of the three extracts, as reported by some, would seem to confirm this.

The *pancreatic secretion* performs undoubtedly an important part in metabolism, and although some researches have seemed to show that Beard's claim for it in cancer was not well founded, the matter should be again investigated, possibly along the dietary lines herein considered.

Very much more could be given in regard to the metabolism of cancer, did time permit, but enough has been said to show that there are gross perturbations of the system connected with this disease, and that the local tumor is but an expression of one aspect of a constitutional disorder, which if unchecked tends to death, aided undoubtedly by a virulent poison secreted by the malignant cells of the tumor, when it has once developed.

Everything has its beginning, but, as Ribert says, "no one has ever seen the beginnings of mammary cancer," nor of any other malignant lesion, and we are in utter ignorance of the first change which takes place when a cell or cells take on a rampant or malignant action. But whenever or however it takes place the impetus must be from the plasma bathing the cell which was previously normal and innocent. We have not time to discuss the subject of "embryonic rests," which quite probably have to do with the genesis of the disease. But these are now known to be common anatomical or histological elements, many of which are present in every one, and which are ordinarily quite harmless. It is, therefore, quite unreasonable to ascribe the cause of cancer to them alone—there must be some deeper, underlying cause which excites them to take on and continue malignant action, and that cause is found in the perverted blood and lymph stream resulting, as several writers have affirmed, from a prolonged violation of the laws of perfect health, although other evidence of this may not have been previously recognized in the individual patient.

It is more than probable that a local irritant is the exciting cause of the starting up of the aberrant action of some particular cell or cells. These then go on multiplying inordinately, destroying adjacent tissues, and finally break down, instead of forming normal tissue. But the local irritant cannot explain why, when once started by local injury, the cells should pursue such a progressive, aggressive, and invasive course. The reason is found, as Sir Astley Cooper and others have believed, in some faulty condition of the system, which is now shown to be from a perverted metabolism, arising from many causes, and among others from overindulgence in animal protein, coffee and tea, and alcohol.

It would seem, therefore, that for the development of the local manifestation of cancer (the tumor or new growth) three elements are requisite, namely: 1. A predisposition or suitable blood condition. 2. A local stimulation or irritation of the part affected, *upon*, 3. The site of an "embryonic rest."

In but a relatively small proportion of cases can the direct local irritant be made out with certainty, and even in cancer of external parts, as the breast, there is often no consciousness of external injury or even a blow, while in cancer of internal parts this is very seldom recognized. I am quite aware that cancer may follow gastric ulcer, that gall stones may act as an exciting cause, and fecal impactions in intestinal diverticula are the starting point of cancer, etc. But the relative rarity of such occurrences shows that there must be some hidden, underlying, constitutional cause which feeds the deranged cells. I appreciate, also, the part which metastasis plays in spreading the disease to distant parts, but this is because generally the faulty metabolic cause is allowed to continue, for when this is checked by proper dietary and other treatment even metastatic foci disappear.

We come now to the question as to what this metabolic disorder is which incites formerly normal tissue cells to take on and continue this diseased action, which is really the true problem in cancer. Alas, the actual and exact state of blood which leads up to the disease has not yet been fully determined, although all that has been learned and already briefly alluded to under the metabolism in cancer, points clearly to the lines of study which should be more closely followed. And even if we should be long in establishing a definite and true metabolic disorder, or should never determine it, this should not deter us from acting on clinical grounds, from experience, even as is constantly done in regard to many other ailments, illustrations of which will readily occur to every one. Indeed, how constantly diseases are treated empirically, with greater or less success, without any great knowledge of their real etiology.

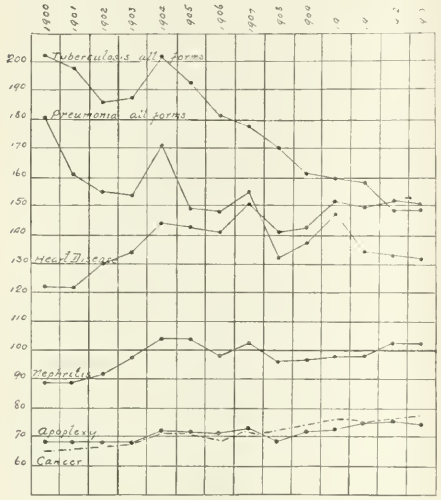
Coming now to the important question of the prophylaxis and treatment of cancer to which this study of its medical aspects leads, we find that we have advanced far toward a proper understanding of the same. We have seen that cancer is but a wrong development of certain previously normal body cells, possibly "embryonal rests," by a process of agamogenesis, dependent upon excessive and faulty nutrition. Laboratory and other studies have decided pretty certainly that it is *not* due to a parasite, *nor* contagious, that it is *not* hereditary, *nor* due wholly to local irritant action, that it is *not* altogether a disease of old age, *nor* belonging to any particular occupation, and that it does *not* affect any particular sex, race, or class of persons, and that it occurs all over the earth, but with striking difference in frequency according to certain peculiarities of life, associated with advancing civilization. We have been thus forced, by exclusion, to recognize that it must be due to some systemic change, whereby the perverted nutrition offered to certain irritated cells causes them to take on a morbid action, which is prolonged by a continued mal-nutrition, and increased or aggravated by a vicious secretion from these diseased cells themselves, in other words, that it is a disease of faulty metabolism.

It will be interesting and instructive to consider for a moment some of the other diseases which are also causing a constantly increasing mortality, as shown by the accompanying table, taken from the volume of the United States Mortality Statistics. These are all recognized as due to faulty metabolism, induced by advancing so-called civilization.

It is seen here that while the death rate from infectious diseases, tuberculosis and pneumonia, has declined steadily and rapidly, that of organic heart diseases has risen greatly, and nephritis has shown a steady rise, as also apoplexy. This latter has about kept pace with cancer, which has risen from 63 deaths per 100,000 living in 1900 to 78.9 in 1913, a gain of 15.9 per 100,000 in 13 years, or over 25 per cent.

If we accept the fact that the mortality of these diseases is steadily rising from the effect of modern civilization, we must also admit that cancer, whose mortality is increasing coincidently, is due to the same cause. And as these diseases are recognized to be largely the result of erroneous eating and drinking, we find here a corroboration of the claims now set forth in regard to cancer. It seems incredible that the profession has so long ignored or rejected the facts showing a constitutional origin

of cancer, and have persisted in regarding it as a local disease, and have so long trifled with it, by seeking to remove the *results of the disease*, while neglecting to rectify its cause; for in spite of active and intelligent surgery the death rate advances with sure and steady steps.



Organic heart disease, nephritis, and apoplexy show a continual and great rise in mortality, and cancer has a coincident rise of over 25 per cent. As the three former are recognized to be largely due to the incidents of modern civilization, mainly in the line of erroneous eating and drinking, it would seem reasonable to ascribe cancer to the same cause.

Prophylaxis of Cancer. From what has preceded it can readily be understood that the prevention of cancer lies largely along dietary and hygienic lines, including such medical attention as shall secure healthy action of the secreting and excreting organs. If the figures and facts obtainable are correct, if cancer has surely been observed to increase under certain conditions of life, if it is found to be absent or relatively rare under certain other conditions of living, if cancer has been known to disappear spontaneously in certain individuals, especially when they have changed their mode of living, it must then follow that when the exactly correct habit and state of life are continually maintained, the disease will not occur.

In other words, when the blood stream nourishing the tissues is ideally correct, the individual cells of the body perform their functions normally, and as each cell is worn out it is removed by a healthy catabolism and renewed by a normal anabolism, and homologous cells replace those which have ceased to be able to perform their function. On the other hand, when there is perverted metabolism we have various forms of deranged action, to which we give the names of various diseases, one of which is cancer. Here in place of homologous cells, maintaining the tissues in a normal condition, we have a malignant metamorphosis into heterologous cells, which take on a disorderly or rampant action, and refuse to assimilate themselves to others, so as to form healthy tissue; we have then a mass of low vitality tending to easily break down and ulcerate, and to extend their malignant action to adjoining tissues, under the continued influence of a contaminated blood current.

Time does not permit further elaboration of this important subject, the details of which must now be patent to all. They are included in a simple living, with perfect mastication, reasonable exercise, the avoidance of all excesses, especially along the lines of protein, tea and coffe, alcohol, etc., with the maintenance of healthy habits of life, especially in regard to bowel action. The greatest safety is with an absolute vegetarian diet, with the single exception of butter.

The medical treatment of cancer can be put in a few words, although in individual cases it may involve the most assiduous attention to the most minute particulars regarding the individual in many directions, and over a greatly prolonged period of time; no detail of the patient's life can be too small or insignificant to have some bearing on the deranged metabolism which affects the cancerous growth, for good or bad.

There is, of course, no single remedy for cancer, nor will there ever be, because of the true nature of the disease, as I have tried to outline it. For the same reasons I cannot believe in a successful serum therapy, it seems so illogical, and the very multiplicity of the forms of serum which have been lauded from time to time, only to end in disappointment, would seem to point toward ultimate failure, when all possibilities along this line have been exhausted.

The first element of treatment is an absolutely correct vegetarian diet, with the avoidance of coffee and alcohol in every form.

But it is not enough for the physician to simply direct that this be taken, but to be thoroughly successful every detail must be carefully attended to so that the patient receives adequate nourishment. The details of this cannot be dwelt upon, and the matter is fully considered in various works on food and nutrition. A vegetarian diet needs no defense, for millions of human beings naturally live thus, and escape cancer, and thousands in civilized lands are adopting it for health. But there must always be care taken, not only that sufficient calories are consumed each day, but also that there is a daily proper amount of vegetable protein, carbo-hydrate, and fat in a form and condition to be acceptable and well digested. A good part of the fat required can be supplied by butter, of which one quarter of a pound should be taken daily, representing 800 calories.

It would surprise you if you knew how almost invariably cancer patients are constipated and have long been so. Indeed, with me it is such a great exception to find it otherwise that I have come to look upon this feature of imperfect intestinal excretion, or intestinal stasis, as it is now called, as one of the prime elements in the causation of cancer. This has been strongly emphasized by Sir Arbuthnot Lane, the distinguished English surgeon, who has spoken of cancer as one of the terminal results of intestinal stasis. I feel almost like saying that the toxins produced by the millions of microorganisms generated through intestinal stasis and fecal putrefaction are the real, incidental cause of cancer.

The kidney secretion is also found to be at fault in every case of cancer which I have studied, and is, of course, an indication of the faulty metabolism which prevails in these cases. It is necessary, therefore, to study this excretion repeatedly and most carefully, in all possible directions, in order to understand the exact condition of the patient, as it changes, daily or weekly. This does not refer

to the presence of albumen or sugar, for I have seldom found these in my cases, but it relates to the total amount of solids thus excreted daily, and to the various component parts and their relation to one another. I have already mentioned that I seldom find the total amount equal to that which should be passed in proportion to the body weight of the patient, although often the quantity of the urine may not be far from normal.

For this purpose a very thorough volumetric analysis should be made weekly of the urine, which should be measured and recorded daily, as is the routine in the hospital and in many of my private cases. The measured volumetric acidity is very important, as also the urea, chlorides, phosphates, sulphates, indican, etc., and the treatment should be guided thereby, the aim being to secure a return to metabolic health. Alkalies form a very important part of the treatment of these cases, but details cannot be given for want of time.

We have seen that the blood presents great changes in cancer, and this should be studied weekly, and iron or other remedies given as indicated. The weight of the patient should also be taken weekly, and while it is often desirable to reduce those who are corpulent, more commonly the weight is watched to improve the nutrition by proper dietary or medicinal measures, which cannot be here dwelt upon.

If time permitted I wanted to give you in detail reports of some of the many cases which I have had, mainly in private practice during the last thirty and more years, for it is hard to carry out satisfactory treatment in hospital cases for a sufficient length of time to be sure of positive results, but I must content myself with very brief mention of the same.

I will not weary you with statistics, but only state that I have a hundred or more records of cases in my office, and a considerable number in the New York Skin and Cancer Hospital, where I have taken up this special line of investigation and treatment during the past year. In about one-quarter of the cases in private practice, there had been previous surgical removal, with recurrence; many of the other cases were small, early tumors, but some of them quite far advanced before treatment, some even with much ulceration and metastatic adenopathy. In almost all of them other medical men, often several, had previously diagnosed cancer, and in a number of instances surgical operations had been arranged for. So that while the diagnosis could not be confirmed microscopically in a large share of cases, there could be little doubt as to its accuracy. And even if possibly some few of the cases were only simple adenoma of the breast, the dissipation of this by non-surgical measures avoided an operation which might possibly be followed by cancer, as has happened in certain cases which had been shown microscopically to be only adenoma after removal. In addition to the cancer cases there were also some 22 other breast tumors which were not included among the former. I will briefly mention a few of the cancer cases:

Case I.—Mrs. B. E. C., aged 44, was first seen on September 12, 1892. She had a flat painful tumor in the outer lower segment of the right breast, pronounced cancer by a well-known prominent surgeon, who strongly urged its instant removal. Within six months the breast became perfectly normal, and remained so for sixteen years, when I lost sight of her.

Case II.—Miss B. M. L., aged 45, was first seen January 4, 1894, with a painful tumor in the upper outer quadrant of the left breast, diagnosed as cancer by three medical men, one of them a surgeon of prominence, who had arranged for surgical removal the next day. Within two months the tumor was less distinct and flatter, but it did not entirely disappear for eleven months. She was seen from time to time also for sixteen years, and had had no recurrence, the breasts being both normal when examined at the end of that time.

Case III.—Miss J. M. A., aged 45, was first seen October 12, 1905, with a tumor of the upper, inner quadrant of the left breast, awaking her with pain at night, which had been repeatedly diagnosed as cancer by different medical men and surgeons, the latter insisting on its surgical removal; but she had always declined operation. Within two months there was little to be felt in the breast, and on January 6, 1906, three months from the first, it had quite disappeared, both breasts being perfectly normal. She has been seen for various troubles, up to the present time, over nine years, and remains perfectly free from any breast trouble, in spite of hard work and worry all the time, as a city missionary.

Case IV.—Miss G. M., aged 44, has been under constant surveillance and treatment for various troubles since she was first seen, November 13, 1905, up to the present time. She had a tumor in the upper, inner segment of the left breast, with enlarged axillary glands: several medical men had diagnosed it cancer, and a hospital surgeon of prominence had pressed for an immediate operation. Within four weeks the painful sensations had almost passed away, and the tumor had diminished materially in size. A month later the breast was almost the same as the other, with some general caking in both. During these nine years she has been busy as a public school teacher, and although troubled with rheumatism, etc., there has never been any recurrence of the tumor, although at times there is caking of both breasts with the menstrual period: the axillary adenopathy has long ago disappeared. Her sister, aged 60, has just died with cancer of the stomach in a distant locality. I could give many more such cases, less striking perhaps, but time allows only of brief mention of some cases which had recurred after operation.

Case V.—Miss H. M., aged 61, came to me June 21, 1913, with multiple nodules in the tense skin left after removal of cancer in August, 1911, further surgical operation being out of the question. Under very active treatment, including thyroid and *x*-rays, many of the tumors disappeared, though some reformed and were removed under local anesthesia, the wounds healing kindly; she lived comfortably, under frequent observation, without pain, for sixteen months, and then was lost sight of, as she was doing very well and wanted to take the *x*-rays nearer her home, some distance from the city.

Case VI.—Mrs. W. C., aged 45, first seen November 17, 1914, was twice operated on at the New York Skin and Cancer Hospital, and came to me with some hard, recurrent lumps, reddened and immovable, quite inoperable. Under faithful treatment she has been very well, without pain, and doing hard work at house cleaning, etc. She is yet under treatment, and lately a new lump has formed, though the others have subsided materially: but she experienced no pain and during these five months has worked very hard, without much or any concern regarding her trouble, except to follow out treatment faithfully.

One case treated in the hospital, with very careful laboratory studies, is worthy of mention, on account of the remarkable improvement occurring in an apparently hopeless case.

Case VII.—Mrs. C. M. was first seen February 12, 1914, with cancer of the right breast, which had been operated on twice, on November 14, 1912, and January 16, 1914. When seen there was ulceration with many nodules around, the liver was enlarged to two inches below the ribs, hard and nodular; the right arm was enormously swollen and helpless. When she left the Hospital, against my wishes, June 20, 1914, in four months, the ulceration had entirely healed, many of the nodules had entirely disappeared, and the arm had returned to normal size, like the other, by measurement, and the liver had retracted to a trifle below the margin of the ribs, with hardly any nodules to be felt. While in the Hospital careful laboratory investigations were made according to a definite daily and weekly schedule, which cannot be detailed here. Suffice to say the blood

improved from 3,262,000 erythrocytes on entering, within two months to 4,282,000 and the leucocytes fell from 9,000 to 5,200, with many other improvements in her condition.

I must just mention one more private case, which though fatal showed the remarkably good effects of careful medical treatment, when a primary case has advanced far beyond the possible aid of surgery:

Case VIII.—Mrs. M. B. J., aged 68, was first seen February 17, 1914, with an enormous hard, cancerous mass in the right breast, the size of half a large melon, ulcerated under a crust over much of the surface, and with immense axillary and supraclavicular adenopathy. This had been kept concealed until the day before she called, and she was profoundly cachectic. In a short time the discharge beneath the crust ceased, the breast became softer, and on August 15, it was recorded that it was soft and movable, and not larger than the other breast, with no discharge, and no pain since a short time after beginning treatment; the axillary glands had diminished three quarters in size, and the supraclavicular glands were much smaller. She died with pulmonary edema on September 9, having had practically no inconvenience from the breast during the seven months of treatment.

Our time does not permit any further consideration of this most interesting and important subject, and I fear that I have trespassed already too greatly on your patience. But feeling as I have for many years, with a constantly growing confidence in my thesis in regard to the cause of cancer and its proper treatment, and with increasing experience, I cannot do otherwise than urge all whom I may, to investigate and see if the claims I make are correct. I know well that I am going contrary to the commonly accepted ideas in regard to cancer, and that very much work will be necessary before the views here presented will be adopted and acted upon sufficiently to check the steadily rising mortality from this terrible disease. But if the facts and statistics which I have referred to are found to be correct by others, it is not too much to hope that, within the next generation at least, the mortality table will show a decline more or less commensurate with that which has taken place in regard to tuberculosis and pneumonia, and we will no longer have the frightful death rate of 90 per cent. of cancer victims.

531 Madison Avenue.

SPEECH-ELEMENTARY SOUNDS.

By A. L. BENEDICT, A.M., M.D.,

BUFFALO.

"CONSULTANT IN DIGESTIVE DISEASES, CITY AND COLUMBUS HOSPITALS; ATTENDANT MERCY HOSPITAL; EDITOR "BUFFALO MEDICAL JOURNAL."

An apology is usual whenever one departs from his established line of work. It may be contended that speech, as evidence of nationality, social condition, etc., is a diagnostic matter applicable to every specialty, that it is affected by pathological conditions of the mouth, pharynx, etc., which may logically be considered parts of the alimentary canal; that it is one of the matters which belong to the general field of medicine irrespective of specialization. The real reasons for the selection of this subject for the present paper are, however, a personal interest antedating even the study of medicine and the observation in an editorial capacity, that it is neglected as a subject for original medical articles and that, in text books on general physiology and on practice even in the specialty commonly designated laryngology, it is sometimes omitted, usually very casually discussed, sometimes with an obvious misconception of facts and principles. Having made this criticism, it is only fair to state that this article is written with no idea of its being considered beyond criticism. It is merely the same mixture of appropriation of the discoveries of others, of some little original study, of truth and error, of information and of ignorance —appreciated or itself ignored—which are characteristic of most medical papers.

Speech is preeminently a human characteristic. It is possessed by no lower animal except in the sense that parrots, a few other birds, and very rarely domestic quadrupeds, may be taught to imitate human speech to a limited degree and possibly to use words intelligently. No race of man has been known that does not possess speech, although it may be admitted that there was a primitive man that did not possess it. It should not be confused with the limited range of inarticulate cries of most voice-possessing animals, expressive of the primitive emotions. Such cries are, to some extent characteristic of all animals; usually of all members of a given species irrespective of geographic distribution and isolation; they are possessed by man also and, unlike speech, are usually identical without regard to distribution and isolation which have produced so marked diversity of language.

Speech should be sharply distinguished from voice. The latter consists of sound waves produced by the vibration of the vocal cords, usually during expiration. Speech consists of various added sounds, produced by muscular control of the supralaryngeal air passages. These cannot properly be termed harmonics, since they are absolute and bear no relation to the tones of the laryngeal voice. The vowels may perhaps be termed overtones since they are continuous vibrations, although they have no mathematic, harmonic relation to voice. The consonants, however, whether continuous or not, consist in checks and modifications of sound, of a still different character, to which it is difficult to apply a definition, although this has been attempted.

That speech and voice are entirely distinct, though usually or at least often coincident, is shown as follows: (1) In whispering, the laryngeal cords are not in action. (2) After laryngectomy, or any condition interfering with the action of the vocal cords, speech is perfectly preserved, unless, of course, there is simultaneous mutilation, paralysis or other interference with the speech organs themselves. (3) After any extensive mutilation of the supralaryngeal portions of the respiratory tract, including both nasal and oral passages, and notably after resection of large portions of the superior maxilla, voice remains in perfect condition barring the interference with resonance from the superior air cavities, while speech is more or less interfered with. As some linguists have compromised on the notion that vowels are produced in the larynx while consonants are pretty obviously produced by supralaryngeal vibrations, it may be definitely stated that resection of the superior maxilla interferes with the production of most vowel sounds. In one case observed no ordinarily recognized vowel sound could be formed—merely the neutral vowel of unaccented *e* in French, the vocalized *r* as in burr, the vocalized *l* as in table, and the undifferentiated vowel sound so frequent in unaccented English syllables, for which we have no letter and which is, indeed, scarcely recognized by the majority of linguists.

The vowels are continuous vibrations, each of definite and arbitrary pitch,* without reference to the general pitch of the voice. They apparently consist of vibrations by resonance, of a chamber consisting of the pharynx, the hard palate and the tongue, the adjustment of this chamber to a given resonance being made by the tongue, a highly muscular organ. Vowel sounds are also formed in nature and in the vibration of various artificial noise-making vehicles, machinery, etc. Strike any surface and it will emit a vowel tone or note the sound of a passing vehicle, of a waterfall, etc. The common onomatopoietic words squeak, bang, click, boom, etc., exemplify the range of tones corresponding to vowels.

In their normal, relaxed state, the walls of the vowel-chamber happen, on the average, to be tuned to the tone represented by *ah*—the original *a* of most languages. Possibly we may explain the tendency to deepen this tone to *aw*, as in Dutch, to elevate it in pitch to approximately the English *a* in ask in Spanish, to hesitate between the Spanish *a* and the English *a* in hat in French, and the development of the Yankee "flat" *a* or of the standard long *a* of English in general, by racial averages in the development of the facial bones. Individual tendencies toward mispronunciation may be similarly explained. The fairly general tendency to vowel decay in many languages, notably in Greek and English, which is generally in the direction of elevation of pitch of a given vowel, as we compare ancient and modern pronunciations, is quite plausibly explained on the theory that change in diet and conditions of life generally have gradually diminished the size of the vowel chamber, so that each vowel has been sharped, somewhat analogously to the development of concert pitch from the physical standards of vibration.

While there is theoretically an almost infinite range of possible vowel sounds, those generally recognized may be tabulated as follows:

	Ah	
Not		At
Aw		Air
But		Bet
Oh		Ate
Put		It
Boot		Meet

Those in the first column gradually descend in pitch by lengthening of the vowel chamber, while those in the second column gradually ascend in pitch by shortening it, the former by depression of the jaw and flattening and projection of the tongue, the latter by raising the jaw and the middle portion of the tongue.

All of the primary vowels occur in English, but some do not occur in various other languages. The short O of not is, by many persons, not differentiated from *ah* and we have curiously inconsistent tendencies to make it *aw* or *ah*. Thus, many persons say dawg, lawg, but cahg, hahg, etc. God is usually pronounced Gahd in swearing, Gaud in praying. Analogously, the distinction between *a* in at and in hair is not marked. The latter sound should not be confused with the pronunciation of *a* as a diphthong ending in short *i* (in it) sometimes before *r* (the letter *i* being usually interpolated merely as a sound-indicator to distinguish from *ah* as in are) and before *g* and *ng* as in bag and bang. There is a good deal of difference of opinion as to whether these words should be pronounced with the simple short *a* or whether the pronunciation *ba i* (short) *g* and *ba i* (short) *ng* is correct.

It will be noticed that the vowels are arranged as long and short, which strikes most of us as natural, yet it is hard to say just why these terms are used. Certainly they do not refer to actual time of pronunciation, which may be literally short for long vowels and protracted for short vowels.

Umlaut vowels.—These are analogous to musical chords of two notes. That is to say, pairs of vowels each short or long in the undefinable sense, and of corresponding place in the opposite ascending and descending scales of pitch, are pronounced simultaneously. A in ask, calf, bath, etc., is a coincident pronunciation of *ah* and *a* in hat, although many persons give it merely the latter sound. Many English and a few American persons make this sound by combining *aw* and the long *a* of air. It is a question whether the Spanish *a* and the broader pronunciation of the ordinary French *a* is the umlaut combination of *ah* and short *a* or a sound strictly elementary and intermediate between *ah* and short *a*. The umlaut combination of *u* in but and *e* in met is commonly heard in French in the sound of *eu* while the long umlaut of the same pairs is represented by the German *ö*, but the long sound may be heard in French and the short in German. The next pair of umlaut combinations, *u* in put plus *i* in it, or *oo* in boot plus *ee* in meet, is represented by both the German *ü* and the French *u*, but both are usually long.

Terminal semivowels.—It will be observed that for the sound of *oo* as in boot, the vowel chamber is at its longest, with the jaws somewhat apart, the tongue flat at the bottom of the mouth and the lips may even be protruded, while for *ee* as in meet, the tongue is arched up nearly to the top of the hard palate, with its tip depressed to get it out of the way, thus making the minimum length of vowel chamber corresponding to the highest pitched resonance. Paradoxically, a combination of these two chambers occurs for the umlaut *ü*, the tongue being contracted so as to allow the air to escape at its sides so that there is a double resonance of *oo* and *ee*. If, at these limits, the vowel is pronounced very quickly, we have a consonantal checking of the air current, corresponding, respectively, (1) to the English *w* or (ancient) Latin *v* or (ancient) Hebrew *vav*, (2) to the English *y* or Latin or German *j*, (3) to a combination of these two, not heard so far as the writer knows in any language but easily formed by anyone who has mastered the umlaut *ü*. While it is not absolutely necessary to protrude the lips in forming either *oo* or *w*, there is a natural tendency in this direction, and, hence, to the degradation of the original Latin *v* to its modern sound in English, Italian, etc., or to that of *f* as in German. This change occurred in Latin, probably in early Imperial times, and it also occurred quite early in Hebrew. The *j* has shown a greater permanency but has deteriorated to a guttural aspirate in Spanish, to a sound represented by French *j* and common in English but without any fixed method of representation, and to *d* plus French *j* in English.

Liquid semivowels.—These are *l* and *r*, formed

*While each vowel has a characteristic, fixed pitch, this varies to a considerable degree, as does the "fixed" pitch of a musical tone. C, for example on different instruments. Vowels may be flatted or sharped through carelessness or personal incapacity, just as a musical note may be.

by vibration of the tongue held at one of two fixed points, either in contact with the anterior arch of the hard palate for *l* or stiffened by muscular contraction at its posterior part for *r*. Either *l* or *r* may form a whole syllable without any vowel in the limited sense. In most languages, *r* is not thus used, and in English, purists insist that bird, err, etc., and various other words be pronounced with a distinct vowel, and linguists often declare that the vowel sound in burr is identical with that in but, but the latter is not the case and, in ordinary pronunciation, there is no sound of a vowel except that inherent to the *r* itself. *L* as a vowel is heard only in unaccented syllables in English, but there is no reason for this limitation except usage.

The nasal element.—Usually, in speech, the expired air issues almost entirely through the mouth, not enough passing through the nose to cause an audible vibration of the upper pharynx and nares. Any vowel may be nasalized, either as a matter of individual or racial habit or on account of some defect of the palate. A general nasalization of speech is made in imitating the inevitable enunciation of those with cleft palate, in Yankee and Yiddish dialect imitations, etc. Nasalized vowels are found in American Indian languages but, otherwise, so far as the writer's limited acquaintance with languages goes, only in French. The nasal French vowels correspond to *o* (on) *u* in but (un), *aw* or at least *o* in not and *ah* (en) and *a* in hat (in). All the vowels may be easily nasalized and it should be clearly understood that the nasal vibration is not simply an added *n* but a supplementary vibration synchronous with the entire vowel sound.

Nasal consonants.—As will be considered more in detail later, most of the consonants may be classified as to location according as there is more or less obstruction to the air current anteriorly, at about the lips, mesially at about the upper incisors or anterior arch of the palate and posteriorly at the posterior part of the palate. If, in pronouncing *p*, *t* and *k*, the organs concerned in producing the characteristic sound are held in position, the expiration of air is stopped, the nares being closed by the faucial muscles. If the latter muscles are relaxed, the air issues through the nose producing three characteristic nasal consonants, *m*, *n*, and a sound represented by *ng* or by *n* before *k* or *g* (or *x*). In regard to *ng*, it may be said that the two letters may either represent the palatal nasal alone or this nasal plus the hard sound of *g*—the former in wringer or finger as pronounced by a German, the latter in finger, linger, etc., pronounced by an Englishman or American. The distinction between sonant and surd, to be described with regard to mutes, is not appreciable for the nasals; neither is any difference as to exact location of the obstacle to expiration through the mouth, as noted in sibillants. In most European languages, the nasals do not precede, in the same syllable, another consonant sound except one formed in or near the same location nor are they used initially before a consonant, though the latter is easy and common in African languages, provided the following consonant is formed at the same spot.

The remaining consonant sounds are susceptible of a threefold classification: (1) according to approximate location of the interference with the air-current anterior or labial; mesial, dental or anterior lingual; palatal or guttural, the former term being rather more correct anatomically. (2) According as the interference consists of an actual stoppage of the air current, with immediate relaxation—mutes or explosives—or of a partial restriction of the air current—sibillants or fricatives. (3) In pairs of surd and sonant consonants according as the obstruction or limitation of the air current involves so firm muscular contraction that no auxiliary vibration occurs or a rather loose contraction, so that such vibration does occur. In German, an intermediate degree is recognized as in ob, Brod, etc., in which the final mute is pronounced half way between sonant and surd. There may, analogously, be an intermediate degree between a mute and the corresponding sibillant, as in the Spanish *d*, pronounced according to grammarians half way fibetween English *d* and *th* in then, or as in the partially successful attempts of foreigners to pronounce the two sounds of *th* or the similar sounds resulting from the attempt to pronounce *d* and *t* with the incisors missing.

What may be generally termed interference consonants may be tabulated as follows:

	Mutes	Sibillants or Fricatives
Anterior or Labial.	B sonant P surd	V F
Mesial or Dental		Th (then) sonant Th (thin) surd
	D sonant T surd	Z S
		(osier) sonant Sh
		sonant corresponding to next Ch (German sound as in Ich) surd
Palatal ..	G (hard) sonant K surd	sonant corresponding to next Ch (German sound as in Buch) surd
		.. sonant, absence of H, smooth breathing in Greek
		sonant, corresponding to next X in native pronunciation of Mexico

The anterior interference consonants may be formed either between the two lips, as *b* and *p*, between the lower lip and the upper incisors, as *v* and *f* by most normal, metagnathous persons (Greek *phi* is said to have been blown between the lips) or between the upper lip and the lower incisors as in prognathous persons. For these three methods, there is no appreciable difference in sound except that the mutes, *b* and *p*, formed between a lip and the opposite incisors, tend to be intermediate between mutes and fricatives.

For the mutes, *d* and *t*, *g* (hard) and *k*, the location indicated is the common one, although they may be formed at sites corresponding to the various fricatives and some languages distinguish them accordingly. The curious duplication of the *k* by *q* in so many languages, probably indicates an original somewhat distinct mute formed farther back in the palate. It will be noted that the mesials shade gradually into the palatals, as we pass from *sh* to the softer German *ch*. The sonant gutturals corresponding to the two sounds of *ch* (German) are not recognized in any language that the writer knows, but are occasionally heard. The smooth breathing, representing like any sonant, a loose contraction or relaxation of the palatal muscles, is really inevitable if the corresponding *h* sound (rough breathing) is not produced or if no contraction occurs at another point of the speech chamber. Thus, it is usually regarded as the absence of a consonant although the Greeks seem to have regarded it as a definite sound and some Hebrew scholars consider that the *aleph* or *a*, originally a vowel, had come to represent the smooth breathing.

The enumeration of elementary sounds is some-

what like the count of the bones of the human body. It has been shown that, in many ways, intermediate sounds may occur, both for vowels and consonants. There are 13 distinct primary vowel sounds, all but two of which are generally used in English, even by those not affecting the niceties of speech—*o* in not and *a* in air. The six combination or umlaut sounds may or may not be counted separately. So, too, any one of the 13 original and 6 umlaut sounds may or may not be nasalized. Hence, we may count the vowels as 13, 19 or 38, according to the point of view.

The terminal semivowels, *w*, *y*, and the umlaut combination of the two may be considered simply as briefly pronounced *oo*, *ee* and *ü*, that is to say not enumerated separately at all, or we may count them as two or three as in regard to the distinction of umlaut vowels.

There are two distinct liquid semivowels, not to mention the variation of *r* from the Bostonian or English partial eclipse of this sound to the French rolling in *Sacrrrrré* nor the special *y* or *ly* sounds of *ll* in French and Spanish respectively, which do not count as separate sounds from those elsewhere listed.

The nasal consonants, unlike the nasal modifications of vowels, are so distinct that they must be counted as three.

There are three pairs of mutes, easily distinguished, without reference to the possible differentiation of sounds according to finer discriminations of place of formation—6.

Similarly, there are eight pairs of fricatives, not counting the alternate methods of forming the *vs* and *fs*—16, but we may subtract the smooth breathing or absence of *h* for reasons stated.

Summing up, the total number of elementary sounds or speech, not counting clicking noises, etc., found in some savage languages, may be counted as 39 up to 78, the difference being mainly in regard to vowels. A conservative count may be considered to be about as follows:

		Present in English
Primary vowels	13	13
Umlauts	6	2*
Nasal element	1	0
Limiting semivowels	3	2
Liquids	2	2
Nasal consonants	3	3
Mutes	6	6
Fricatives exclusive of smooth breathing	15	9
	49	37

*No authoritative distinction between long and short.

Diphthongs and triphthongs will be considered only briefly. In English and most other languages, there are no consonantal tetraphthongs except inclusive of *r* or *l* as a vowel—as in teachers (*t* plus *sh* plus *r* plus *z*). Neither are there vowel triphthongs except with the terminal semivowels, *w* and *y* at the beginning as in the name of the letter *y* (*w* plus *ah* plus *ee*). Consonantal triphthongs are common and follow in English, pretty definite rules of arrangement in accordance with ease of sliding from one position of the speech chamber to another. Theoretically, vowel diphthongs may be formed in any possible combination. Practically, only certain ones are used in most languages. In English, those recognized are *ah* plus *ee* (long sound of *li*), *aw* plus *ee* (*oy*), *ah* plus *oo* (*ow*), *ee* plus *oo* (long sound of *u*), which is rather uncertainly distinguished from the terminal semivowel *y* plus *oo*. Short *a* plus short *i*, as stated, is commonly heard in such words as bag and bang, but there is a question whether this is correct. Continental Europeans criticise the English and even more the Americans for making the long *a* and long *o* diphthongs, by adding *ee* and *oo*, respectively. For example, we ordinarily pronounce bone as boh-oon. The late Dr. Roswell Park was one of the few exceptions encountered by the writer. The Greek *ei* was pronounced analogously to the ordinary American long *a*, but with both components of the diphthong short in sound. While it is ordinarily stated that the Greek *oi* and Latin *oe* were pronounced like English *oy*, and Latin *ae* like our long *i*, it is questionable whether the components of the diphthong did not preserve their original sounds, especially as *aw* is a rare sound in most languages.

It should be clearly understood that this article deals with sounds and not letters. English spelling is notoriously far from phonetic. Only a few sounds are invariably represented by certain letters, and vice versa. Thirteen vowel sounds are represented by 5 letters—supplemented by *w* and *y*—and there are often duplicate methods of representing the same sound and marked irregularities in the clumsy system of indicating special vowel sounds by silent letters. *Q* duplicates *k*, *j* and *x* represent diphthongs—not to mention the confusion of *g* and *j*, of *c* and *s* or *k*, of *s* and *z* and many other inconsistencies. Thus, we have at best 23 letters to represent 37 elementary sounds. An attempt is made to compensate by the use of indicator letters, but even these are not used systematically. For instance, *sh* represents a single sound, so does *th*, but one of two distinct sounds which can be determined only by rules of etymology. *Ch* represents a consonantal diphthong, but neither *c* nor *h* but *t* plus *sh*. *Wh* represents the two sounds indicated by its letters but in reverse order. It is not intended to discuss English spelling further than to point out the futility of a reform with our present alphabet, and for this reason to adhere to historic and etymologic spelling, but merely to caution the reader against being misled in the consideration of elementary sounds, diphthongs, etc., by the appearance of the word in print.

228 Summer Street.

THE EARLY DIAGNOSIS OF STREPTOCOCCIC SORE THROAT, AND THE EFFECT OF VACCINES IN ITS TREATMENT.

By RALPH R. MELLON, M.Sc., M.D.,

ANN ARBOR, MICH.

ASSISTANT PROFESSOR OF PHYSICAL DIAGNOSIS AND DIRECTOR OF THE LABORATORY OF CLINICAL PATHOLOGY, HOMEOPATHIC HOSPITAL, UNIVERSITY OF MICHIGAN.

In April, 1914, I published an article[1] entitled "A Method of Early Diagnosis of Streptococcic Sore Throat." A brief description of the method is as follows:

With a sterile cotton swab, get a representative idea of the organisms present by rubbing it over the tonsils, palate, and as much of the retrotonsillar region as possible. Make smears on cover glasses and cultures on blood agar. (This is prepared by adding one part whole human blood to ten parts 2 per cent. glucose agar.) In place of incubating these tubes for 18 to 24 or even 12 hours, as is usually done, it is preferable to make an examination of the very first colonies that appear on the medium. Eight or ten or these should

be stained in Loeffler's methylene blue and examined. They usually appear in from three to six hours. The tube is then incubated for 18 to 24 hours, and a representative smear of the growth is again examined microscopically.

It was evident that a marked morphological dissimilarity between the smears and the first colonies existed. A 24-hour culture showed about what one would reasonably expect to find from a consideration of the variety of the organisms in the smear. It was interesting to find that the first colonies were in the most cases pure cultures of the streptococcus, while a representative examination of the growth in 18 to 24 hours showed such a mixture morphologically that no satisfactory diagnosis could be logically given.

In all cases which had undergone operation for the removal of the tonsils, the latter had been procured under aseptic precautions, and a thorough exploration of the crypts made. The same procedure was adopted as in examination of the throat before tonsillar enucleation, viz., a direct examination of the cryptic contents, which were then transferred to the usual blood agar, and the first colonies examined. In this way we were able to make comparison with the findings obtained by the swab method.

Aside from the dissatisfaction with the ordinary method, the basis for the adoption of the above procedure lies in *a priori* considerations. Since bacteria are supposed to flourish in the body only in case the soil is favorable for their reproduction, the method of transferring some of this soil to artificial media really represents an attempt to make use of this tenet. In this particular instance, assuming that the underlying infection is streptococcic, it is possible that in case the virulence of this organism was increased, such an event might be roughly measured by the relative length of time it required to appear on the medium.

And when I speak of increased virulence, I mean increased reproductive capacity on the part of an organism, which often is, but may not be, an index to its toxicity. This lately acquired ability of the streptococcus to multiply, by virtue of a lessened aggressivity on the part of the host tissues, can be roughly measured by its rate of growth and the length of the chains that appear in the first colonies of a blood-agar slant. Even in so short a time as 24 hours, the organism loses some of its recently acquired properties, as is shown by the lack of chain formation and the increase in the size of the individual. This is apt to be the case in the acute anginas of moderate severity. However, in those of unusual severity, almost pure cultures of the streptococcus can be seen even after 24 hours. I recently had such a case, in which only after 36 hours did several large colonies of staphylococci develop. Prolonged cultivation on artificial media caused a reversion similar to that which the less toxic undergo.

A second element that I consider of importance in this connection is the length of chains that appear. I am perfectly aware that this contention, considered as a basis of scientific classification, is untenable, and that the length of the chains can be reversed at will by alteration of environmental conditions. Nevertheless, I contend that the environmental are not the sole factors in determining the length of the chains. Even then a partial explanation can be found in the *in-vivo* and *in-vitro* disparities regarding this characteristic. In the throat, for example, the exudative process, combined with the muscular movements of the affected parts, produce a condition of unrest which is not conducive to chain formation. The same is true of these organisms growing in the blood. In bouillon we usually have long chains produced when the medium is undisturbed, but frequent shaking during the course of the growth precludes such formation. Again, the agglutinative powers of the medium, whether it be natural or artificial, are more productive of groups of diplococci than of long chains. Nevertheless, we took particular care to guard against environmental errors by making our media as constant a factor from every standpoint as possible. It makes a difference whether whole blood or blood serum is used, as the latter is certainly more conducive to the formation of long chains. In experiments being done at present whole blood and serum-agar are being used in a parallel way, but, of course, not interchangeably.

As favorable evidence for the validity of this method, I have detailed the experiences of two epidemics of acute streptococcic sore throat, in which 75 cases were studied. These cases were all treated with a stock streptococcic vaccine whose immunizing capacity was good. The throats were examined bacteriologically at the end of from three to six weeks, using the method above described. Examinations of normal throats at that time served as controls.

Some of the conclusions of the article are as follows: This epidemic of sore throat occurring in Ann Arbor two years ago gave rise to a method which at least was successful in an early diagnosis of the affected cases by an examination of the first colonies that appeared on a suitable medium. As evidence in favor of the efficiency of this method we have (1) the results of the specific vaccine with control cases in which no vaccine was used; and (2) the return, bacteriologically, to normal of the affected throat. It would seem that there is a relation between the virulence of the organism and the length of the chains, although such relation is not proportionate. In this connection it is hoped that this method will apply to ordinary sore throat and, at least in those which are due to the streptococcus, give an early indication of its presence in a virulent condition. I am glad to state that for some time past we have applied this method to about forty of these cases, and the results so far have corroborated our earlier studies. This series of cases, with the additional ones that are accumulating, will be reported in the near future if there is justification for such a report.

In the past two and one-half years we have examined a number of throats, both acutely and chronically inflamed. In all cases the method above indicated was employed, and many cases received vaccine treatment.

For the sake of clearness I have made an arbitrary division of my cases into four groups. They are, of course, subject to the overlapping that is common in any attempt at biological classification. In Group I. I have placed those in whom the tonsils were quite large, although the patient did not show any constitutional symptoms which are known to be related to pathological tonsils. Group II comprises all grades of ordinary sore throat, follicular tonsillitis, and arthritic involvement the severity of which depends on the epidemic. Included in this group are those following operation on the nose. The symptoms did not follow in the

first 24 hours after operation, and hence were not strictly postoperative. They usually made their appearance in from three to four days following operation. The patient suddenly developed a sore throat, a temperature of 103° to 105°, accompanied by a moderate degree of prostration. Usually the temperature fell gradually and recovery in a week was the rule.

Group III comprises cases which have always been regarded as normal, and Group IV contains those cases in which the arthritic symptoms were prominent, and the tonsillar involvement insignificant, at least from a gross viewpoint.

The first group, containing fifteen cases, was quite uniform in showing findings which could in no way be separated from those of perfectly normal throats. The fact that we rarely found long chains of streptococci in the first colonies from the crypts of such tonsils was also significant. In addition, it was certainly not the rule to find hemolytic cocci in these crypts.

Group II comprises 25 cases. The symptoms were often those of follicular tonsillitis, and the cases varied from those showing only local symptoms with slight fever, to ones with marked constitutional depression. The smears from the tonsillar surface showed a great increase in the number of intracellular and extracellular diplococci, which occasionally occurred in short chains. Very often bacilli of varying size were found, and occasionally those of the true Klebs-Loeffler type were encountered. The mouth spirochetes and the *M. catarrhalis* were usually present also.

The first colonies usually showed chains of streptococci which varied in length from 10 to 100 cells. Very often these organisms were hemolytic and sometimes they showed a large capsule, but they never fermented inulin. It should be noted that the large majority of organisms were arranged in chains, but there were, of course, many diplococci. In some few cases the diplococci were associated with or outnumbered by the *M. catarrhalis*. In one case true Klebs-Loeffler bacilli constituted the predominating organism in the first colonies, although this patient did not develop true diphtheria. The 24-hour cultures consisted mainly of grouped diplococci, although rarely the chain form of the organism predominated. A later examination of these throats (three to eight weeks) showed only diplococci in the first colonies, corresponding in every particular to normal throats.

The vaccine results in these acute cases were interesting. For the most part they responded very quickly and decisively. A moderate local and constitutional reaction occurred which was soon followed by a decrease in temperature, as well as a marked improvement in the subjective symptoms and the general condition of the patient. Case No. 1 was subacute and showed splendid results. In this series of cases the results were obtained independently of the use of gargles, with the possible exception of hot salt solution. In a previous communication I have expressed myself in regard to the use of gargles in these acute cases. With the exception of the reagent above mentioned, suffice it to say that local measures from my experience are entirely unnecessary.

I have obtained the best vaccine results by employing strains of streptococci of proved immunizing powers. These are not necessarily autogenous, but they are certainly not to be regarded as stock vaccines in the ordinary sense of that term. I have lately used a strain of *Streptococcus viridans* isolated from a case of scarlet fever which gave better results than the ordinary autogenous vaccine, not only in the throat cases but in the other streptococcus infections as well. The organism was of mild virulence for rabbits but the serum of these animals developed strong immunizing powers. I have also isolated a strain from an old abdominal wound which gave similar results. But streptococci from many other conditions, though virulent, were useless as vaccines. I believe the autogenous preparations should be used whenever possible, unless one is fortunate enough to have at hand a strain which has a high immunizing potential.

It is well known that virulence and immunizing power are not necessarily synonymous. I have isolated some streptococci from cases of septicemia which have been utterly worthless for immunizing purposes. The conditions which are necessary to produce a good immunizing strain are very imperfectly understood at present, and it belongs as a part of the future development of the science of immunity to devise constant results in this regard. Any method which will produce the most secondary and tertiary groups (in the sense of Vaughan) and eliminate the toxic group of the protein molecule should give the best immunizing response. At present Besredka's method[4] of sensitizing vaccines appears promising. Gay,[5] of California, extracts a poisonous substance from the sensitized typhoid bacillus and uses the extracted sensitized sediment, which he claims gives a greater immunity than any method yet devised in typhoid fever. Its application to this more universal infection will, it is hoped, improve the antigenic powers of the vaccines.

Group III contains a series of twenty cases having presumably normal throats. The smear practically always showed a mixture of organisms. Although the proportion of the different kinds varied, it was unusual that the predominating organism was not a diplococcus. The first colonies were composed almost entirely of grouped diplococci, the individual organisms being quite large (involution forms). The 24-hour culture showed a very luxuriant growth, with the diplococci predominating, although not infrequently the bacilli and staphylococci occupied the foreground.

Group IV contains twenty-five cases. It was noteworthy that the tonsils in these cases were usually small and somewhat lobulated. Sore throat and recurrent tonsillitis, although having a place in the patient's history, were certainly not the presenting features, either subjectively or objectively. Constitutional symptoms were quite marked, the joint involvement being foremost, although albuminuria and cardiovascular diseases were by no means infrequent.

The smear examination showed nothing abnormal except in cases having frequently recurring tonsillitis, and in those who had recently recovered from attacks. In such instances the number of intracellular diplococci was increased, and some extracellular short chain formation was present. The same could be said of the first colonies. If the attacks were so frequent that the mucosa seldom returned to normal for any length of time, the first colonies were apt to show chains of considerable length. In the 24-hour culture the diplococci predominated regardless of the length of the chain displayed by the first colonies.

Cultures of the crypts from the 15 cases of this

group which underwent tonsillar extirpation showed in every case a pure culture of a streptococcus which was often hemolytic. The first colonies, as well as the 24-hour cultures of some of the strains, showed long chain arrangement.

Analysis.—An examination of the bacteriological findings of this series of 65 cases of tonsillitis, with 20 cases from normal throats to serve as controls, shows that my contention is of value in acute cases of tonsillitis, no difference whether they are acute exacerbations of a chronic tonsillitis, cases from epidemics, from postoperative sore throat, or "hospital sore throat" which is such a common contagious condition among nurses.

However, the method is of no value in cases of chronic tonsillitis, either with or without constitutional symptoms, but an examination of the crypts of enlarged tonsils in these cases almost invariably shows a pure culture of the streptococcus, which manifests varying grades of hemolysis. These findings are in accord with those of Davis,[6] who places emphasis on this point. He says: "The bacterial flora of the tonsils, as revealed by a study of chronic cases, is usually strikingly different from the flora of the crypts. They may occasionally be similar, but usually are not. Subcultures as ordinarily made from the surface of the tonsils, especially in chronic infections, are quite unreliable for determining crypt flora."

However, it is still a question how much biological difference exists in these cases between crypt cocci and throat diplococci. If there is constantly an exchange of cocci from the throat to the crypts, and vice versa, the difference would not seem to be so great. But the fact that in the same case one may find intracryptic hemolyzing cocci which in the first colonies often give rise to long chains, while the extracryptic cocci do not have these characteristics, gives rise to the idea that the former are more pathogenic. Davis and Rosenow have constantly produced arthritides in rabbits by injection of intracryptic cocci as well as by tonsillar emulsions, but what proportion of extracryptic cocci would produce arthritis I do not know.

In the last two years we have had over 100 cases of sore throat in nurses alone, and in practically all instances the streptococcus was the causative organism. I think that there can be no doubt that the "hospital sore throat," an occupational disease long known among nurses, is merely one of the varied manifestations of the activity of this organism.

During the two years following the milk epidemic sore throat there was an unusual number of cases of acute tonsillitis following operations on the nose, but also after other operations. Practically all cases were streptococcic, the virulence and toxicity of the organism being probably induced by a trauma of the neighboring tissue or by a direct extension of the inflammation.

That most cases of tonsillitis, whether chronic or acute, with their attendant sequellæ, are due to this organism there can no longer be any doubt.

Summary and Conclusions.—1. An early examination of cultures from acute sore throat is valuable because it precludes an overgrowth by contaminating organisms, and because it often gives a clue to the virulence and toxicity of the infecting agent.

2. Although of advantage in acute and subacute cases, it is of no value in chronic ones.

3. Our ideas as to what constitutes a normal mouth and throat must undergo revision. Because one does not have any condition in his oral cavity which causes pain is not proof of the bacteriological normality of that cavity. His tonsils make him a streptococcus or diphtheria carrier, just as surely as one who harbors the typhoid bacillus is a carrier of that organism. It is now well known that streptococci may develop a focus in the gums and around the roots of the teeth, as well as in the tonsils.

4. Examinations of the oral cavity should look to a more careful interpretation of the organisms found there. If the work is done with the adherence to the limitations above mentioned, valuable information may at times be derived. The relation of hemolytic cocci to the arthritides and the *S. viridans* and the pneumococcus to endocarditis (Rosenow) necessitates the use of blood agar for this work, as it affords a ready clue to that particular member of the group with which we have to deal. In the chronic cases cultures of material from the crypts and animal inoculation may often clear up the diagnosis of many so-called cryptogenic infections.

5. The acute cases of streptococcic sore throat respond very quickly and decisively to a vaccine of proved immunizing powers. Provided the vaccine was used early, it has not been my experience so far to see any case of this condition develop any of the numerous complications which may sometimes occur.

It is not my intention to laud the merits of stock vaccines because, generally speaking, the autogenous are the logical therapeutic agent. But certain strains of this organism often yield much better immunizing results than are seen with the autogenous vaccine. If one is fortunate enough to have such a strain at the time it is needed, there is no justification for the autogenous preparation; otherwise it would seem advisable to obtain the latter as early as possible.

It is true that many cases apparently recover without any treatment, but if the many sequelæ could be followed up in every case, we might revise our notions on the self-limiting ability of this disease.

Because the apparent symptoms of one attack have been eliminated it is by no means a proof that such an attack has not laid the body liable to the more stealthy changes which result from the continual absorption and ingestion of these organisms.

Who at present would have the temerity to say how many cases of arthritis, nephritis, etc., have had their origin in repeated attacks of sore throat, each of which was supposed to have limited itself, but which was merely the flare-up of a smoldering focus of infection?

In closing, I wish to express my appreciation for the valuable technical assistance rendered by Mr. H. C. Allen and Mr. W. R. Voigt in the performance of this work.

TWO CASES OF DEPRESSED NASAL DEFORMITY RESULTING FROM THE SUBMUCOUS OPERATION.*

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,

NEW YORK,

RHINOLOGIST AND OTOLOGIST TO BELLEVUE AND ALLIED HOSPITALS (GOUVERNEUR HOSPITAL.)

As the history bearing upon the etiology of the deformity in both of these cases is practically the same, they will be considered together.

Both of these men are healthy and neither has ever had syphilis or any other constitutional disease. One is nineteen and the other forty-one years

of age. Both were suffering from nasal obstruction, due to deflected septa. One had the submucous operation performed one and a half years ago and the other two years ago. *In neither case was the operation followed by suppuration.* Both patients were operated upon by men of recognized ability.

Though the patients quickly recovered from the immediate effects of the operation, shortly afterwards the cartilaginous dorsum of the nose dropped in and marked depressed deformities resulted.

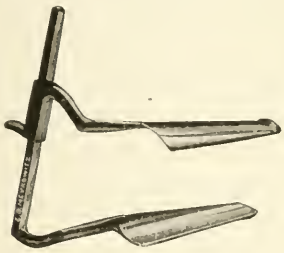
Examination of these patients shows that the upper edge of the septum where it should lie wedged in between the two lateral cartilages, has either been dislocated or removed from this position.

These two cases are reported not altogether because of the interest attached to them as clinical exhibits. They are shown chiefly for the purpose of emphasizing a point in connection with the technique of the submucous operation which I tried to impress upon the profession a number of years ago, when I devised and advocated the use of the first punch-forceps intended for the removal of the septum.

I have always maintained that we should consider first the relief of the nasal obstruction and that the

intranasal cosmetics should be held as a matter of secondary importance; and, further, that only that portion of the septum should be removed which interferes with free nasal respiration and drainage.

This removal of the septum should be accomplished by means of an instrument which shall remove a circumscribed and definite amount of tissue, and without traction upon the remainder of the septum. This can be done only by means of a punch-forceps. Forceps having a pinch bite cannot accomplish this, no matter how sharp the edges may be. Any instrument used in removing the septum which produces traction may dislocate the upper edge from its position between the two lateral cartilages where it acts as the keystone of the cartilag-



inous arch. The dislocation of this means a depressed deformity, such as you see in these patients. This deformity can be properly corrected only by the transplantation of bone or cartilage.

Personally, as far as I know, I have never had a case where deformity resulted from this operation, and I feel that this immunity has been due largely to the care I have always exercised in preserving the integrity of the nasal arch by protecting the upper edge of the cartilaginous septum.

During the past year I have seen several cases similar to the ones I have shown to-night and the number of these deformities is increasing with the spread in popularity of the submucous operation. This accident is, to a large extent, avoidable, and should be carefully guarded against, for it casts a reflection upon one of the most artistic and useful operations in rhinology.

REPORT OF A CASE OF PANOPHTHALMIA OCCURRING DURING PNEUMONIA.

By ROBERT L. PITFIELD, M.D.,

PHILADELPHIA,

VISITING PHYSICIAN TO ST. TIMOTHY'S AND GERMANTOWN HOSPITALS.

The case detailed here is one of pneumococcus infection, interesting because of the widespread fields of invasion and because of the extreme virulency of the infection or of the lack of defensive mechanisms of the individual affected and because of the rarity of the total eye infection and involvement.

Always during the acute course of pneumonia there is a bacteremia which persists until just before the crisis. Then some chemical process, with a dampening effect akin to a wet blanket on a blazing fire, snuffs and smothers out the infection and if there is sufficient vitality and sound organs the patient recovers. There are many cases in which there is no crisis, of course, and many who die after the crisis. In the instance here related this immunity process was too feeble and failed to stay the invaders, or else the type of the pneumococci was too virulent to be affected by any protecting process in the blood stream.

From the lungs, a focal infection appeared in the meninges, the eyes, again in the lung previously invaded but nearly well, and probably in the endocardium.

B. H., female, aet. 15, was admitted to St. Timothy's Hospital suffering from meningitis. There were delirium, headache, vomiting, retracted head, rigid neck and limbs, tache cérébrale, and a diagnosis at first hand needed but a glance. All signs of meningitis were present save the scaphoid belly. There were coarse râles in the apex of the right lung and brownish sputum, and from the history it was apparent that there had been pneumonia in this site.

Her history was that of an overgrown school girl, who had been subject to repeated infections of the tonsils, having had chorea and rheumatism. Evidences of an old endocarditis were manifested by a marked two and fro apical murmur, thrill, and shock too marked to be very recent; besides the history of previous dyspnea confirmed this view.

On entrance to the ward she had a leucocytosis of 33,400, albumin blood and casts in her urine. Negative Widal reaction. On spinal puncture, cloudy spinal fluid was obtained which was largely composed of polynuclear cells, and many pneumococci globulin was also detected. No tubercle bacilli were found either in the fluid or sputum.

Physical examination revealed a young girl with wide staring prominent eyes, with retracted neck, flushed cheeks, having some play and quivering of the nasal alae, adenitis of the postcervical chain and a full thyroid. Her chest was well developed and expanded freely and rapidly. The cardiac movements were perceptible through the walls, the apex was in the sixth interspace and the heart dullness was increased an inch to the right and outside the nipple line on the left. There were a double mitral murmur, a marked thrill, and diastolic shock. The sounds were very rapid and labored, but regular. The lungs were normal, save for some fine râles throughout and an indefinite area of dullness in the right apex posteriorally, and with coarse bubbling râles and blowing breathing like a resolving lung which it seemed to be. The abdomen was slightly distended but otherwise normal, save that the liver was slightly enlarged, spleen could not be felt, kidneys not tender on palpation. Her extremities were cold, cyanotic, rigid. The reflexes all were heightened and abnormal even such as Babinski's and Oppenheim's present, also Kernig's sign. There was marked catatonia and no edema.

Over night on the eleventh day, her eyes seemed to bulge more, and were injected, the corneas were hazy and the fluid in the anterior chamber was milky and there was much edema of both eyelids. Evidently, there was present from this data and from a very unsatisfactory view of the fundus and vitreous, an acute exudative cheroiditis. The right lung became again consolidated from bottom to top, delirium was constant and wild, sordes gathered in the teeth, carphalogia and subsultus tendinum appeared. The patient had to be restrained on account of her delirium.

On the fourteenth day of illness, the eyes became more swollen, and lids were highly edematous, the optic bulbs appeared like two boiled white onions. Pneumococci were found in the pus in the coniunctival sac. Her breathing was very rapid, also the pulse, spine absolutely rigid, feeding by nasal tube from the entrance to the hospital. Active stimulation, hydrotherapy and intravenous infusion of salt solution were resorted to. Argyrol, boric acid, dionin, and atropine were employed unavailingly to the eyes. On the sixteenth day the girl succumbed to her disease with acute edema of the lungs as the terminal expression. There was evidently a pneumococcal meningitis, with pneumonia and panophthalmitis of both eyes due to the pneumococcus infection. The outlook for life was always grave, and for her sight extremely bad. It was well perhaps that she died.

A NEW MEASURING BOARD FOR INFANTS.

By RUDOLPH DURYEA MOFFETT, M.D.,

NEW YORK.

ASSISTANT VISITING PEDIATRIST IN THE GERMAN HOSPITAL AND DISPENSARY, ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN HOSPITAL DISPENSARY.

THE accurate measurement of the infant is of recent development from a purely scientific standpoint. It has been, however, of interest for the mothers to know the height or length of their babies. Being impressed with the necessity of something that would more accurately measure the length of the baby, I devised a measuring board

upon which you can measure the length of the baby not only in inches but in centimeters. This measuring board was constructed for me by the Kny-Scheerer Company of New York, and is made of light oak, along the center of which there is a wooden scale of centimeters and inches. Along both sides are two boards so as to prevent the infant from falling off the measuring board. The head of the baby is placed at the end marked "A," and the part marked "B" slides along in the grooves against the feet so that when the part marked "B" comes in contact with the feet the number of inches can be recorded from the scale. The illustration shows all of these points fairly well, and where scientific work is to be carried on this measuring board is of special service.

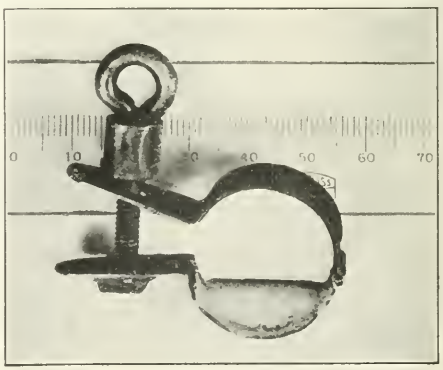
830 Park Avenue.

A URETHRAL CLAMP FOR POST-OPERATIVE URINARY INCONTINENCE, DEVISED AND MADE BY A PATIENT FOR HIS PERSONAL USE.

By ABR. L. WOLBARST, M.D.,

NEW YORK.

THE clamp shown in the accompanying illustration was designed and manufactured by hand by a patient in the Genitourinary Outpatient Department of Beth Israel Hospital. The man is 82 years old, and for several years has been suffering from urinary incontinence, the sequel to a perineal prostatectomy. By day he wears a rubber urinal, but



he found it impractical to wear this cumbersome apparatus during the night. As a result, necessity being the mother of invention, he set about to find a way to control the involuntary outflow of urine while he slept.

Being a coppersmith by trade, he made the clamp about to be described entirely by hand of sheet brass. It is made of two arms or lips, joined together at one end by a hinge. Through the center of the terminal lips, he fitted a thumb-screw, which when turned to the right engages a nut on the under side of the lower lip. This nut is soldered to the lip, thereby strengthening the thin layer of metal and at the same time giving it a sufficient thread to provide a proper purchase. The upper arm or lip of the hinge is concave and smooth, and its edges are turned up so as to form a flange, thereby preventing cutting or chafing of the skin with which it comes in contact. The lower arm has its concavity filled in with a piece of sheet metal in such a manner as to form a smooth, convex, semi-cylindrical surface. Between the lip and thumbpiece, is a solid brass collar which keeps the thumb-screw from hugging the lips and thus making it awkward to operate. The metal is 0.635 mm. in thickness and 12 mm. in width. The entire clamp weighs about one ounce.

The method of use is interesting. Before retiring, the patient attaches the clamp to the penis, just behind the glans, the body of the organ fitting snugly into the concavity of the upper lip. The smooth straight surface of the lower lip makes gentle yet firm pressure on the urethra, as a result of which, when the clamp is closed by means of the thumb-screw, not a drop of urine is allowed to escape. So that when he retires and clamps the urethral canal tight, the urine gathers in his bladder and in his urethra as though he had a natural sphincter. When he feels full, he awakes, gives the thumb-screw a few turns to the left, thereby removing the pressure upon the urethra, and empties his bladder in the normal manner. He tightens his clamp again and is once more ready for several hours of sleep.

The ingeniousness of the little apparatus, its skilful manufacture, and the age of the patient all combine to justify this detailed report of a surgical curiosity.

113 East Nineteenth Street.

Medicolegal Notes.

Labeling Bottles Containing Poison—Evidence. — A practising physician in a mining camp where there was no drug-store or pharmacist not only prescribed but compounded his medicines. One of his patients went to his office complaining of a stomach trouble. The doctor prepared for him a mixture of nux vomica, which he put in a two-ounce bottle of a brown color. In an action against him for negligence for failing to label the bottle the doctor testified that he pasted upon it a label with the written direction: "Take five drops in water after each meal." He also gave the directions verbally to the patient. Some weeks after, the patient's wife went to the doctor, suffering from some menstrual trouble. He prepared a remedy for her, which he put in a brown three-ounce bottle, but without placing any label on it he gave it to the patient, telling her that the dose was a teaspoonful as needed. After about half the contents of each bottle had been used the wife took a teaspoonful out of her husband's medicine-bottle, which she thought contained her medicine. Almost immediately she went into convulsions. The doctor was called and reached her in about an hour. By that time she had returned to consciousness, and told the doctor that it was the time for her monthly sickness, and that she had taken a dose of the medicine which he had prescribed for her. The doctor assumed that she was suffering only from her female trouble, and no doubt attributed her marked improvement to the efficacy of his medicine. With her husband he went to his office and sent back some pills. On returning, the husband gave his wife another teaspoonful of the medicine out of which she had taken the first dose an hour before, and which all supposed was the bottle prepared for her a month before by the doctor as a remedy for her female trouble. The medicine again threw her into convulsions, and the doctor was hastily summoned. From the symptoms his suspicions were aroused, and he examined the bottle and discovered the mistake. At that time this bottle did not have a label on it. The doctor administered an antidote and in a few hours the patient recovered consciousness and was out of danger, though she suffered ill-effects for several days. There was evidence to indicate that her health was permanently impaired, although there was a conflict in the proof on that point. She sued the doctor for $5,000 damages. The case was squarely submitted to the jury on the question as to whether the doctor did or did not place a label on the bottle of poison. The jury returned a verdict for the doctor. This was affirmed on appeal, where it was held that under the Kentucky statute the trial court properly refused to allow the husband to testify that the defendant labeled the bottle, the exception to the statute permitting a husband to testify for his wife in any matter in which he acted as her agent, not being applicable.—Nicholson vs. Patrick, Kentucky Court of Appeals 170, S. W. 20.

Malpractice — Insufficient Evidence. — In an action against a physician for causing a miscarriage by electrical treatment applied when the plaintiff was advanced in pregnancy about two months it appeared that, while the treatment was being administered, the plaintiff went to a drug store, and purchased, without a physician's prescription, an ounce bottle of extract of cotton root, the contents of which she took in certain doses. On appeal from a judgment for the plaintiff, it was held that, as the evidence left it purely conjectural whether the proximate cause of the miscarriage was the electrical treatment or the extract of cotton root, judgment should have been entered for the defendant notwithstanding a verdict for the plaintiff. The court quoted from the opinion of Mr. Justice Taft in Ewing v. Goode, 78 Fed. 442, another malpractice case, as follows: "When the burden of proof is on the plaintiff to show that the injury was negligently caused by defendant, it is not enough to show the injury together with the expert opinion that it might have been caused by negligence and many other causes. Such evidence has no tendency to show that negligence did cause the injury; when the plaintiff produces evidence that is consistent with an hypothesis that the defendant is not negligent, and also with one that he is, his proof tends to establish neither."—Coombs v. James, Washington Supreme Court, 144 Pac. 536.

Proof of Employment.—In an action to recover for services as a surgeon in operating on the defendant, removing his prostate gland, etc., it appeared that the defendant first consulted his physician as to the advisability of calling some one else and the physician called the plaintiff, who told the defendant he would perform the operation and the defendant assented. This evidence was held sufficient to show that the plaintiff was employed by the defendant.—Meany v. Anglemire, 189 Ill. App. 357.

Practising without Authority—Clairvoyant.—Massachusetts Rev. Laws, c. 76, §9, provides that the provisions of section 8, prescribing a penalty for one who, not being lawfully authorized, practices medicine, shall not apply to a clairvoyant, provided he violates none of the provisions of section 8. In proceedings for practicing medicine in violation of section 8 the defense was that the defendant had acted as a clairvoyant. There was evidence that two men called on her for treatment; that while asleep, holding the patients' hands, she gave advice to the first and told the second the nature of his sickness; and that in both cases she furnished the patients with medicine for which they paid her. She testified that when consulted by a patient she went into a trance and that while in the trance she was told by "occult force" what the matter with the patient was and what remedy to prescribe; and on coming out of the trance she prescribed what had been revealed to her while she was in it. It was held that the word "clairvoyant" must be confined to its ordinary meaning, namely, a person who sees, while in a trance, things which by reason of distance or for other reasons are not ordinarily visible, and, so construed, section 9 does not authorize a clairvoyant to prescribe medicine revealed to him by "occult force" while in a trance.—Commonwealth v. Delow, Massachusetts Supreme Court, 106 N. E. 846.

WAR BRIDES, ILLEGITIMACY, AND LEGALIZED ABORTION.

It is quite in keeping with the extreme sex consciousness of the present era that considerable discussion should be aroused by some of the unhappy consequences of the Great War, so far as these affect the sexual and domestic life of the millions of people involved in the struggle. Surprisingly varied are the phases in which the problems of sex have presented themselves. Shortly after the outbreak of the war the expression "war brides" sprang into being, typifying these women who married their soldier lovers on the eve of the latters' departure for the front. There were, indeed, preached from many pulpits in England sermons advocating the speedy marriage of all engaged couples, and in several districts marriage fees were remitted in order to facilitate the welding of the bonds of matrimony. The aim of all this was to ensure an ample harvest of new lives to take the place of those that would inevitably be lost on the field of battle. In this campaign for a more accelerated racial productiveness the dramatist has perceived valuable material for his pen.

War, with its vast cataclysmic upheavals of society, brings to light and intensifies many evils that exist during peaceful times. Illegitimacy is one of these. The cry has already been raised in England that the concentration of soldiers in different parts of the country has been accompanied by a vast increase in illicit sexual indulgence—a fact not new in history—with the result that there will soon be born a large number of offspring of these irregular unions. It would appear that Nature accomplishes in a simple manner without the ceremony dictated by religion and convention an object for which publicists and sociologists diligently strive. At any rate, the plight of the "unmarried mothers" has already been made the subject of an eloquent appeal to the British nation. Ronald McNeill, in the London *Morning Post* of recent date, writes that "thousands of young girls are nearing the ordeal of womanhood, racked with shame and with terror of the cruel censure of the world they live in." And what of the children? "Are they, the offspring of the heroes of the Marne, of Ypres, of Neuve Chapelle, to carry through life the stigma of shame for 'irregular' birth? Are they, who on eugenic principles, should be the most virile of our race, to be handicapped from the start by impoverishment both of physical constitution and of moral character, through the ignorance, prejudice, and injustice of their earliest environment?" The appeal is made that the children "be boldly adopted as the honorable children of the State" rather than "that they should slink through life as the children of shame and the parish." Undoubtedly this plea for the expectant girl mothers will reach many a sympathetic ear. But how, may it be asked, will it be possible to distinguish between the general run of illegitimate children, of which England can boast a goodly crop even during peaceful times, and those whose fathers are alleged to be soldiers fighting under the colors? Surely the wisdom of Solomon would not be equal to the task.

This problem of war-time illegitimacy has also arisen in France. L. Tissier, a noted obstetrician and authority on medicolegal topics, contributes to the *Journal de Médecine et de Chirurgie*, March 25, 1915, the text of a discourse on this subject that he has recently delivered before the Medicolegal Society of Paris. He calls attention to the principle known in French jurisprudence as the "reconnaissance du ventre," according to which a man can certify before a notary that he is the father of an infant, conceived but not yet born. Since the outbreak of the war there have been many instances in which a uniformed soldier appeared with his mistress at the bureau of birth records and signed a declaration affirming that they are the parents of a child that is to be born. The object of this legal formality assures to the mothers those bounties provided by the government for the future mother if the father is serving in the army. Besides, in case of the death of the father the illegitimate child whose paternity is acknowledged participates in any inheritances to the extent allotted to an illegitimate child; it is also entitled to the pension accorded to the child of a soldier who has died in service. Tissier proposes the adoption of another principle into the body of jurisprudence, a principle the exact antithesis of the one described above, and designated "la méconnaissance au ventre," the repudiation of the unborn child. This would have to do with those instances in which a married woman whose husband is serving with the army has been ravished by one of the enemy. Tissier would accord to the husband the right to declare that he is not the father of his consort's child, a right that it is difficult to conceive any chivalrous Frenchmen would care to exercise, even though the real father were a German.

This brings one to the subject of the State sanctioning abortion in the case of women violated by the enemy. Rape is one of the evils that has followed all warfare from the dawn of history, and it is one of the unhappy consequences of the present war. The German medical journals have published discussions as to the propriety of the State permitting abortion in the case of any woman violated by one of the enemy, but the consensus of the best opinion in Germany has been that the State could not sanction this procedure. The same opinion appears to prevail in France. Tissier, in the same journal, cited above, presents the arguments

against this legalized abortion for other than therapeutic purposes, as follows: The bearing of a child is not only the consequence of conception. The entire organism of the female feels the impress of impregnation. The performance of abortion cannot remove this effect. It would be better to permit the unfortunate victim of alien lust to bear the fruit of her conception to term and then to abandon it clandestinely to the State. At any rate, abortion would not remove the stigma of violation; at the same time it would subject the victim to an added danger.

THE ETIOLOGY OF GASTRIC AND DUODENAL ULCER.

One of the most perplexing problems with which the medical profession has had to do is that concerning the etiology of gastric and duodenal ulceration. The theories that have been advanced are numerous and, strange to say, many of them are founded on what appears to be good experimental evidence. On one point only are most of the investigators agreed. That is that the incidence of ulceration of the gastric or duodenal mucosa depends primarily upon some definite disturbance in the circulation in a limited area. Wilkie has found the cause of such disturbance in the occurrence of retrograde embolism in the radicals of the portal system draining the stomach and was able to produce ulcers by the injection of almost any insoluble powder into the veins of the omentum. Rosenow is of the opinion that the ultimate cause is infectious in its nature and he has been able to produce chronic ulcers by the intravenous injection of streptococci which had been isolated from ulcers of the stomach. He assumes a specific elective affinity of such organisms for some tissue in the stomach wall and that the result of their activity will be chronic ulcer formation, and furthermore he appears to have excellent experimental evidence in favor of his contention.

The latest theory is that propounded by Friedman (*Jour. Med. Research*, 1915, xxxii, 95), who has pointed out the value of the red cell count in the diagnosis of ulcer showing that with duodenal ulcer there is usually a polycythemia while in the majority of cases of ulcer of the stomach the blood shows an anemia. Several investigators had already noted that injection of epinephrin was followed by a temporary increase in the erythrocytes of from thirty to one hundred per cent., so that Friedman was led to try the effect of repeated injections of epinephrin upon animals. Of twelve dogs which received repeated injection of epinephrin, eleven developed lesions of the duodenal mucosa. Five controls showed no such lesions. He therefore is of the opinion that an excessive secretion of the adrenal gland might have a selective action upon the mucous membrane of the duodenum and that such result is to some extent due to the fact that the duodenum receives its innervation through the sympathetic system. Some experiments seem to show that the duodenal region is more irritable to mechanical and thermal stimulation than the rest of the small intestine, which would explain the selection of the duodenum rather than portions of the gut further down. The lack of increase in the blood pressure he explains by arguing that the increase in adrenal action may be so slight that the blood pressure is not affected but that when prolonged, even this slight increase may be able to bring about the structural changes which he found. In additional support of his theory he mentions that partial extirpation of the adrenals in dogs and rabbits has resulted in lesions in the stomach.

It is quite difficult to correlate the experimental results of these investigators. It is possible to imagine that in a given individual, some strain of streptococcus proliferates actively in the tonsils and eventually finds its way through he gastrointestinal tract. The organisms then may work their way through the walls of the gut into the portal radicals and their location in the stomach or duodenum be determined by the excess or deficiency in the adrenal secretion. This is however pure imagination, and all these theories will need a tremendous amount of testing. The clinician unfortunately, is left in exactly the same position in which he has always been—the cause remains unknown. The reports are stimulating however, and it is to be hoped that many workers will take up the task of finding the truth which must be hidden somewhere in this material.

THE INFLAMMATORY TUMORS OF THE ABDOMEN.

Scant attention has been paid to this subject in the textbooks of surgery, and only within the past ten years has it provided a theme for articles in the periodical literature. One of the most noteworthy of these is Arnsperger's paper on the inflammatory tumors of the sigmoid flexure. Lejars has written on the inflammatory pseudoneoplastic tumors of the abdomen; Moynihan and Mayo Robson have referred to the simulation of malignant disease within this cavity; Futh has described a pseudocarcinomatous infiltration of the intestinal wall accompanying disease of the adnexa; and these and other surgeons have reported similar conditions involving the stomach, liver, biliary passages, and other viscera. Jaroski, Heymann, Küttner, and Hofmeister have reported cases of inflammatory processes beginning within the abdominal cavity and finally involving the wall of the latter in a distinct neoplastic formation.

Gino Baggio contributes an important study on this subject to *Il Policlinico*, Sezione Chirurgica, January and February, 1915, and reports two cases of his own. He points out that in some of the instances cited there was no real tumefaction, but simply a conglomeration of various viscera to one another or to the abdominal wall. In other cases the inflammatory mass consisted of an extensive proliferation or infiltration. Any one of a number of morbid factors was held responsible for the condition; usually it was the extension of an inflammatory process involving the lining or wall of the gastrointestinal tract. This tendency to a wide diffu-

sion of the growth often made it difficult or impossible to differentiate the condition from a malignant neoplasm, more especially in cases in which a marked cachexia was present. As a rule diagnosis was impossible without the aid of exploratory laparotomy and subsequent microscopic examination. The ideal treatment is summed up in the words "noli me tangere." In thirty-seven out of forty-seven cases simple abdominal section sufficed to effect a cure. In ten cases the mass was resected and in four of these death followed the operative procedure.

A special group of cases of inflammatory tumor of the abdomen comprises those secondary to the presence of a foreign body either in the lumen or in the wall of a hollow viscus. In the latter instance the inflammatory mass frequently develops at the site of some operative cicatrix usually the result of the presence of suture material that has not been absorbed. There have been reported in the literature a number of cases in which a migrating foreign body was responsible for the tumor formation. Similar to these cases, both clinically and pathologically, are those in which abscesses with a small amount of pus develop in the walls of the viscera or in the abdominal parietes, the extension of neighboring or propagated from remote infective foci.

Although inflammatory tumors of the abdomen are relatively rare, they are of eminent clinical importance in view of the fact that they are usually diagnosed as malignant growths. It is quite likely that some of the instances of spontaneous disappearance of visceral cancer have really been instances of inflammatory tumor undergoing spontaneous involution.

Recent Views on Arteriosclerosis.

Several years ago Klemperer, representing the clinicians, announced his opinion that alcoholism played a dominant rôle in causing arteriosclerosis. Whereupon Von Orth, the successor of Virchow, representing the pathological anatomists, took Klemperer severely to task for his generalization. A very large percentage of arteriosclerotics, he said, showed at autopsy a complete absence of the more direct evidences of chronic alcoholism, such as gastritis, fatty liver, alcoholic colon, and the like. In this connection it is interesting to note that in a recent study of this subject, read before the United Medical Societies of Berlin (*Berliner klinische Wochenschrift*, March 8) Klemperer represents the newer teachings rather than the traditional ones. Arteriosclerosis is a disease chiefly of the intima. Experimentally it can be set up by certain toxic substances (adrenalin, aliphatic aldehydes, lactic acid). In mankind the frequency of the disease in the gouty and diabetic is ascribed to catabolic toxins. Powerful toxic substances, such as alcohol and tobacco, may act as contributory causes. Acute infectious diseases, especially in the young, play a very decided rôle, as does syphilis. But experimentally bacteriotoxins cannot cause the affection. As yet, Klemperer asserts, we have no proof that a meat diet can cause arteriosclerosis, though he admits that continuous high blood pressure can produce it, and an excess of animal protein in the diet is believed to be one cause of high blood pressure.

Psychopathology of Desertion.

Experts attribute desertion in time of war to temporary affects, rather than to any special lack of ethical levels. In other words, the act of running away in time of battle may not differ radically from the poriomania of epileptics and obsessives. Specht, however, in a paper read before the Military Medical Society at Erlangen (*Muenchener medizinische Wochenschrift*, February 23) stated that he found no epileptics among his deserters, although these men were clearly psychopathic degenerates, and known as such even before the war. Three cases are cited, one of which was a substitute reservist. He deserted, was captured, and submitted to a mild punishment. His condition was that of psychogenic stupor. When set free he committed suicide by drowning. The second case was in an imbecile, noted in peace time for running away, who had also deserted before the war. He is now in an asylum. A third subject is a mental and moral defective, and alcoholic degenerate. He deserted when drunk and was found eight days later in a swamp. It appears that men of this type, not being taken at the period of mobilization, are accepted later as volunteers largely because of their great patriotic fervor, which suggests the old quotation to the effect that patriotism is often the last refuge of certain undesirables.

News of the Week.

Mme. Depage.—Many surgeons and others in America have been greatly shocked and grieved by the death of Mme. Marie Depage, wife of Dr. Antoine Depage, Chief of the Red Cross of Belgium, who lost her life in the *Lusitania* atrocity. She had been in this country on a mission for the Belgian Red Cross and had renewed many old friendships and made countless new ones among Americans of all classes, and especially among members of the International Congress of Surgeons, of which her husband was president. With her was lost over $100,000 which she had collected for the Red Cross needs in her country.

Report of the Treasurer of the Committee of American Physicians for the Aid of the Belgian Profession.—The following contributions were received during the week ending May 8, 1915:

The Medical Society of St. Lawrence County, Gouverneur, N. Y.	$25.00
The Orange County Medical Assoc., Santa Ana, Cal.	25.00
Dr. Parke W. Hewins, Wollesley Hills, Mass.	25.00
Dr. Emma B. Culbertson, Boston, Mass.	25.00
Dr. L. L. McArthur, Chicago, Ill.	25.00
Dr. V. B. Jackson, Washington, D. C.	10.00
Receipts for the week ending May 8th	$135.00
Previously reported receipts	6,585.50
Total receipts	$6,720.50
Previously reported disbursements:	
1,825 Standard boxes of food at $2.20	$3,575.00
1,309 Standard boxes of food at $2.30	3,010.70
Total disbursements	6,585.70
Balance	$134.80

American Medical Association in New York City.—The Merchants' Association of New York has started a movement to bring the 1916 meeting of the American Medical Association to this city. It has issued a circular asking physicians to endorse the movement which, it says, is favored by the officers of the A. M. A. Invitations have been extended by all the county societies comprised in the Greater City except the New York County Society, in which action has been deferred. Unless invited by the latter the A. M. A. cannot come, so the Mer-

chants' Association asks that the physicians of this county recommend their society to extend an official invitation to the national body.

Dr. John Dill Robertson has been appointed Commissioner of Health of Chicago to succeed Dr. G. B. Young, U. S. Public Health Service, who retired recently after a successful term of service.

Dr. Richard S. Creel of the U. S. Public Health Service has been offered the position of Health Commissioner of Boston, and at the request of the Mayor the Public Health Service has granted Dr. Creel an indefinite leave of absence in order that he may accept the appointment.

Dr. A. Jacobi was the guest at a dinner given in honor of his eighty-fifth birthday by a number of physicians at the Hotel Astor on May 6. Addresses were made by Mr. Nathan Straus, Health Commissioner S. S. Goldwater, and others. Dr. James P. Warbasse was the toastmaster.

Dr. Otto V. Huffman, secretary of the New York State Board of Medical Examiners, has been elected secretary of the faculty and executive officer of Long Island College Hospital, Brooklyn, as successor to Dr. Joseph H. Raymond, deceased. Dr. Huffman is an alumnus of the Medical Department of Columbia University, 1903. He was formerly pathologist to Sloane Hospital for Women, in New York, and instructor in clinical pathology in Columbia University. Dr. Huffman is also secretary and treasurer of the Federation of State Medical Boards and editor of its publications.

Dr. John W. Wainwright, formerly editor of the *American Practitioner*, has joined the editorial staff of *American Medicine*.

Saved from the Lusitania.—Among those rescued when the *Lusitania* was destroyed were four American physicians—Drs. Howard Fisher of Washington, J. T. Houghton of Saratoga Springs, Owen Kenan of Palm Beach, and F. Warren Pearl of New York City.

A New Medical School for Columbia.—It is announced that Columbia University is going to build one of the largest medical schools in the world on a part of the site which was formerly the American League baseball grounds at 165th street and Broadway, which the Presbyterian Hospital recently purchased. Columbia University and the Presbyterian Hospital have joined forces in the creation of the new school and hospital. The project includes the new medical school to replace the present College of Physicians and Surgeons, and the removal of the Presbyterian Hospital from the East Side to the new site. Columbia University has set five years as the time limit for the raising of a fund of $7,500,000, which will include the cost of its share of the land, the cost of building a new medical school, and an endowment fund for the maintenance of the school.

Washington University Medical School.—The new buildings of the Washington University Medical School, St. Louis, were dedicated with appropriate exercises on April 29 and 30. Addresses were made by the dean of the school, Dr. Eugene L. Opie, President Lowell of Harvard, Mr. H. S. Pritchett and Dr. Abraham Flexner of the Carnegie Foundation, Dr. Welch of Johns Hopkins, Surgeon General Gorgas, Drs. George Dock, R. J. Perry, and William T. Porter.

The Cook County Hospital.—The Chicago *Tribune* states that eighty-eight members of the attending staff of the Cook County Hospital will lose their positions in accordance with a decision handed down by Judge Fornoff in the Circuit Court. He issued a mandamus writ compelling the county civil service commission to restore to their official records an examination held on Dec. 7, 1911. This examination was held by the commission to have been conducted fraudulently, and a new examination was ordered. The eighty-eight doctors were those who passed the later test. The Judge held that while there may have been mistakes made in the marking of one or two of the examination papers, there was no evidence of fraud and no justification for the commission's action in canceling the entire examination.

The American Gynecological Society. — The fortieth annual meeting of this society will be held at the Greenbrier White Sulphur Springs, W. Va., on May 18-20, under the presidency of Dr. Thomas J. Watkins of Chicago. The secretary is Dr. Lehy Broun of New York City.

The Death Rate of New York City.—The number of deaths from all causes reported during the week ending May 1 was 1638, with a death rate of 14.72 per one thousand of the population, as against 1593 deaths and a rate of 14.89 during the corresponding week of 1914.

Fifteen Medical Missionaries Wanted.—The American Board of Commissioners for Foreign Missions needs at once fifteen surgeons and physicians for work in mission fields. Nine are wanted for China, four for Turkey, one for Africa, and, most urgent of all, one at once for relief work in Serbia, with station at Monastir. The candidates should be not over 35 years of age. In equipment the board requires a degree from a distinctly first-class medical school and, in addition, an interneship or its equivalent. Specialization is not demanded, though special preparation is welcomed. Details as to service may be secured from Dr. C. H. Patton, 14 Beacon Street, Boston.

A Study of Mouth Infections and Their Relation to Pyorrhea.—The Bulletin of the New York City Health Department states that an interesting study concerning the relation of certain microorganisms to pyorrhea, and designed to devise, if possible, preventive measures against this condition, is now being carried on at Public School 21 by bacteriologists of the Bureau of Laboratories of the Department of Health. A special class has been organized, consisting of children whose gums show evidences of the possible beginning of pyorrhea. This will be subdivided into several groups, one of which will serve as the control, and the others to be submitted to a definite course of treatment. The course of the condition will be followed both clinically and microbiologically and the investigation promises to yield valuable information.

Societies to Meet in San Francisco in June.—Lowell Otis Reese gives a list in the *Military Surgeon* for April of the following medical organizations which are announced to meet in San Francisco in June:

Pacific Coast Oto-Ophthalmological Society, June 14, 15, 16.

American Society of Tropical Medicine, June 14, 15, 16.

American Association Medical Milk Commissions, June 17, 18, 19.

Pan-American Medical Congress, June 17, 18, 19.

American Climatological and Clinical Association, June 18, 19.

American College of Surgeons, June 21.

Medical Society of the State of California, June 21.

American Proctologic Society, June 21, 22.

American Therapeutic Society, June 21, 22.

American Hospital Association, June 21, 22, 23, 24, 25.

American Medical Association, June 21, 22, 23, 24, 25, 26.

American School Hygiene Association, June 25, 26.

American Academy of Medicine, June 25, 26, 27, 28.

Obituary Notes.—Dr. EDWIN T. M. HURLBUT, formerly of Sebastopol, Cal., a graduate of the University of Buffalo, Medical Department, Buffalo, N. Y., in 1867, a member of the Medical Society of the State of California, and the Sonoma County Medical Society, and a veteran of the Civil War, having served in the Twenty-fourth New York Artillery, died at the Veterans' Home in Napa County, Cal., on April 12, aged 87 years.

Dr. R. SYDNEY CAUTHEN of Charlotte, N. C., a graduate of the Baltimore, Md., Medical College in 1902, and a member of the Medical Society of the State of North Carolina and the Mecklenburg County Medical Society, died suddenly, from heart disease, at his home on March 24, aged 43 years.

Dr. JUDSON ELAM HAIR, JR., of Greenville, S. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1912, died at Mobile, Ala., from tuberculosis, on March 25, aged 26 years.

Dr. JOHN M. GAINES died at Hagerstown, Md., on March 29 at the age of 77 years. He was graduated from Jefferson Medical College in the class of 1860 and he served as a surgeon in the Confederate Army during the Civil War.

Dr. LANDRETH W. THOMPSON died at Philadelphia on March 31 at the age of 52 years. He was graduated from Hahnemann Medical College and Hospital of Philadelphia in the class of 1887. He was for many years surgeon to the Children's Homeopathic Hospital and a member of its Board of Directors, surgeon to St. Luke's Hospital, professor of emergencies in Hahnemann Medical College and corresponding secretary of the Germantown Medical Club.

Dr. WILLIAM H. BUNN died at Philadelphia on April 1 at the age of 75 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1861. He took an active interest in Masonic matters.

Dr. WILLIAM BROOKS BIGLER died at Dallastown, Pa., on April 1 at the age of 81 years. He was graduated from Jefferson Medical College in the class of 1865.

Dr. FRANCIS MANTON HOLLY of Greenwich, Conn., a graudate of Yale University, Medical Department, New Haven, in 1855, one of the founders of the Greenwich Medical Society, and a surgeon in the United States Army during the Civil War, died at his home, from pneumonia, on April 7, aged 82 years.

Dr. MAXIMILIAN JACOBY of Roosevelt, N. J., a graduate of the Long Island College Hospital, Brooklyn, in 1910, died at the Elizabeth General Hospital after a short illness, from blood poisoning, on April 9, aged 32 years.

Dr. ROBERT J. RIVERS of Paducah, Ky., a graduate of the Hospital College of Medicine, Louisville, in 1902, died suddenly in Hopkinsville, Ky., on March 29, aged 37 years.

Correspondence.

SIMPLIFYING HYDROTHERAPY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD of May 1, Dr. Hinsdale's excellent paper refers to the impossibility of standardizing physical therapeutics. This is due to the fact that the premises are inexact in all therapy, chiefly because of physical and psychic differences in patients. That a closer approximation to this ideal may be attained in the application of water in disease, is demonstrated by thousands of observations recorded in the Vanderbilt and Riverside Association Clinics, and in a private institution during the past twenty years, in which the prescriptions were exact, the patients were ambulant, and regular reports of reaction, weight, etc., were recorded. In other words the prescription was written as exactly as is one for drugs and it was executed by attendants trained as well. In fact here was a corroboration of the view expressed in my article on "Fatality of Text Book Hydrotherapy" (MEDICAL RECORD, July 1, 1911) and in my address before the Academy of Medicine on "Management of Pneumonia Patients" (MEDICAL RECORD, Dec. 12, 1914). It was clearly shown that hundreds of cases of sunstroke were lost in the best hospitals by irrational use of ice and cold water, the mortality under this treatment being 33 per cent., while the mortality in St. Vincent's Hospital under O'Dwyer was only 6 per cent., when water, at proper temperature, based on physiological rationale was applied. The same result was shown in pneumonia, when water was used rationally.

Similar inaccuracy and indifference to exact prescription on physiological rationale accounts for the numerous failures encountered in the hydrotherapy of ambulant cases. That the failure due to this may be as easily avoided in ambulant as in the acute cases is evident from the following instances:

1. One justly eminent neurologist almost invariably prescribes for neurasthenia "hot box and charcot douche," leaving to the attendant the duration of the former and the temperature, pressure and duration of the latter. Positive results are impossible.

2. On a recent visit, in an advisory capacity, to a celebrated health resort, I found the arrangements for douches, which had been added, at my my suggestion, eighteen years previously, used in the most unphysiological manner. The hot air cabinet, which is very useful for preparatory skin-heating before the tonic (cold) douche, was out of commission on the male side. A gentleman, who came with a letter from his physician advising tonic baths, was ordered by the Medical Director "electric light box" for two minutes, followed by a douche of 90° F., two minutes. As a result the patient, taking this treatment daily, lost flesh steadily. Why? Because two minutes' stay in the electric light box does not heat the skin sufficiently to induce the necessary temperature contrast for stimulation, when followed by a circular douche of 90°! The patient was cold before entering the douche. He failed steadily, lost four pounds, while his wife, who took tonic treatment, without the doctor's prescription (as is commonly permitted here) obtained a correct tonic bath, viz., "hot air cabinet" until warm (not perspiring) followed by one minute circular douche 95° to 90° F., succeeded by a fan douche at 85° F., daily reduced one degree—"dry with friction." She gained

rapidly. As I have often pointed out, the hot air box heats the skin before perspiration, which always depreciates a feeble patient, ensues. It may, by prolongation, become an active diaphoretic, which is useful in well nourished individuals, and which I always prescribe in what is termed "eliminative treatment" for rheumatic and gouty conditions of the well nourished and for obesity, etc. The electric light cabinet, on the contrary, heats by radiation and *does not warm the patient before perspiration ensues.* It is therefore suitable only for "eliminative treatment." *No one familiar with hydrotherapy ever prescribes a definite duration of the hot cabinet,* because patients differ in their capacity for diaphoresis and their ability to perspire increases day by day. In the application of water, on the contrary, gradual inuring or training is demanded.

Precision may be easily obtained without itemizing by simply prescribing "tonic treatment," which every well-trained attendant knows to be "hot air cabinet until warm, followed by circular douche of one minute 95° reduced slowly to 90, twenty pounds pressure; followed by fan douche, 85° F. (reduced daily one degree), followed by jet douche in the latter days of treatment. Dry with gentle friction. Report in ..... days." This I have termed "neuro-vascular training." It may go on until reaction ensues without friction by nurse, when it may be continued every other day until restoration is secure.

For "eliminative treatment," the prescription used in the clinics and in private practice with satisfactory results for twenty years was "hot air, or electric light cabinet until patient has perspired ..... min.; followed by circular douche two minutes, 100 to 90° F., pressure twenty pounds; followed by fan and jet douche 90 to 85° F. daily reduced one degree, pressure twenty pounds. Friction drying. Report weight, etc., in .....days." The physician need prescribe only R Elim. Treated. Following this exact method (ordering tonic or eliminative treatment, without writing detailed directions) the patient receives a report at intervals, prescribed by the doctor, who may record the effect and increase or diminish the items as he deems best. Of course a trained attendant is as necessary as is a trained druggist. It may be mentioned that this apparatus treatment is appliable only in ambulant cases. In acute hospitals the apparatus is superfluous, as several have learned to their sorrow. See "Principles and Practice of Hydrotherapy," published by William Wood & Co. My home and hospital "vascular training" method was published in the MEDICAL RECORD of July 22, 1913.

SIMON BARUCH, M.D.

51 WEST SEVENTIETH STREET.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HOSPITAL FINANCE—KING EDWARD'S FUND FOR LONDON—RESEARCH ON TROPICAL DISEASES—HOSPITAL SATURDAY FUND—HUTCHINSON'S MUSEUM—OBITUARY.

LONDON, April 23, 1915.

THE annual meeting of the governors and council of King Edward's Hospital Fund for London was held at St. James's Palace on Monday, when the speaker took the chair and the Honorable Secretary (Sir Savile Crossley) read a letter from the King expressing his Majesty's regret at the loss sustained by the fund in the death of Lord Rothschild, honorable treasurer and chairman of the finance committee, and approving, as patron, the appointment, as his successor, of Lord Revelstoke, who has for many years been an active member of the finance committee. Further, the King, gratefully appreciating the services of the governors (the Duke of Teck, Viscount Iveagh, and the Speaker of the House of Commons), in carrying out the duties of president during the five-year term expiring in June, intimated his intention to reappoint them. The Speaker briefly moved a resolution, seconded by Lord Iveagh and unanimously carried, recording the great services of Lord Rothschild during the whole period of the fund's existence. The Speaker next reported that under the terms of the Act of Incorporation it became the duty of the governors to appoint a successor, and they had chosen Lord Revelstoke, one of the original members of the finance committee, who has devoted the most watchful care to the fund's investments and has consented to undertake these additional responsibilities. The King, as patron, had approved of this, as well as of the Hon. Algernon H. Mills as a member of the council, and the Hon. N. C. Rothschild as a member of the finance committee. The balance sheet is quite satisfactory in spite of the financial disturbance occasioned by the war, the total receipts for the year (1914) being over £529,885, of which more than £315,000 were contributed for capital, and £214,000 for general account. The latter amount is made up of annual subscriptions, donations, ground rents, legacies, investments, and sums from the League of Mercy, and several trust funds. In this year of war the distribution was somewhat lower than in the previous year, but not in the amounts given toward maintenance of hospitals, the diminution being due to postponement of building expenditure. During the last ten years this fund has distributed among hospitals, convalescent homes and consumption sanatoria £1,417,750, and since the foundation of the fund a total amount of £1,950,416 8s. 6d.

The King and Queen and the other Royalties support this fund by handsome annual subscriptions, as do several city companies and other institutions. The League of Mercy again gives £14,000, making, since its foundation in 1899, £216,000 besides its contributions to institutions outside the fund's area of work. A further sum has been received in augmentation of capital from the estate of the late Sir Julius Wernker, who was a member of the council. The council express great satisfaction at the amalgamation of small special hospitals, and has continued to promote this desirable policy, which it has long advocated. The report moved by the Speaker was seconded by the president of the Royal College of Physicians (Dr. F. Taylor), and carried unanimously by the well satisfied audience.

Another annual report presented this week is that of the advisory committee of Tropical Diseases Research Fund, which was issued on Wednesday. This committee, you may perhaps remember, was set up in July, 1904, at the instance of the then Colonial Secretary. The chairman is Sir J. West Ridgeway. Last year the revenue was £3,745, toward which the Imperial Government gave £1,000 and the Indian Government £500, the balance being made up by smaller contributions from tropical parts of the Empire. The expenditure reached £4,250, of which the London School of Tropical Medicine took £1,450, the Liverpool School £1,200,

the London University £850, and the Cambridge University £750. The excess over income had to be drawn from the accumulated balance, which is thereby so much less.

The Secretary of State, after consultation with the advisory committee, addressed a dispatch early in the year to the governments which support this fund. In his dispatch Mr. Harcourt pointed out that the period of five years for which grants had been promised had expired, and asked that they might be renewed for another five years, and as they have agreed to this the work will be continued for that period. A further satisfactory fact is that the commonwealth government of Australia requests their Parliament to continue their grant of £200 a year on behalf of the Northern Territory.

Yet another annual meeting the same evening—that of the Hospital Saturday Fund. This was presided over by Sir Vezey Strong, who observed that since its establishment in 1873 the fund had collected and distributed nearly £700,000 among London medical charities. For the last few years exceptional difficulties had been experienced as many people had expected that there would be less need for hospitals after the State had established insurance against sickness. But this was not the case. No help had resulted for in-patients, though there was some reduction in the number of out-patients. The war, too, had affected receipts, absorbing money which might have been subscribed to hospitals of which the work was increased by many wounded from the front. It is hoped subscribers will remember that their benevolence is more needed, rather than less, on account of the troublesome times.

So you are taking from us the remarkable museum founded by Sir Jonathan Hutchinson, which represents the life-work of that industrious clinical observer and collector. It comprises hundreds of colored drawings, plates, photos, engravings and other pictures, with manuscript, and often letter-press descriptions, of such as had been published. Many very rare specimens are among them, for Hutchinson delighted in collecting and comparing such. If we part with it regretfully, it is better for America to have it than any other country.

Chemical skill is not confined to any country, and there is no reason why our manufacturers should have handed over the preparation of alkaloids to Germany. It seems to be a question of profit, or, as our druggists say, of the rate of wages. The Imperial Institute in 1903 called attention to the hyoscyamus muticus which grows freely in the Egyptian desert and offers a source of atropine. Some manufacturers took the hint, but not all. Hence price has gone on increasing with the heavy purchases for the army. The Institute has lately referred to the matter again, and it is hoped that our English firms will not let slip the opportunity of securing the supplies of the plant from Egypt and showing their laboratories are equal to any.

Surgeon-General Aylmer Martin Crofts, C.I.E., I.M.S., died on the 12th inst., suddenly, from heart disease, from which he had suffered a long time. He retired from the service last year, having filled many important posts, among them P. M. O. Rawal-Pindi Division, and Senior M. O. in the China Expedition. He held the Afghan medal and the Khedive Star, the Order of St. John, and that of Philip, and was Honorable Surgeon to the King.

Sir Thomas Clouston, late president of the Royal College of Physicians, died on the 19th inst., at Edinburgh, where he passed most of his distinguished career. His name will be familiar to you as one of the leading authorities on mental diseases. In 1873 he was appointed superintendent of the Edinburgh Royal Asylum, which, under his administration, was recognized as a model of its kind and an excellent training school for medical superintendents and all engaged in the study of the physiology and pathology of the insane. For thirty-five years he lectured on the subject, and was regarded as an able teacher and an active promoter of all benevolent reforms in the care and management of the mentally afflicted. He was knighted in 1911.

Dr. Frederick Taylor is the new president of the Royal College of Physicians.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

SCHOOL FOR MIDWIVES—BUREAU OF HEALTH EDUCATIONAL CAR—CHOLERA IN MINDORO AND ZAMBOANGA—OPPOSITION TO A TUBERCULOSIS SANATORIUM—PERSONAL.

MANILA, February 17, 1915.

ONE of the most practical steps recently taken to secure a reduction of the infant mortality through the islands has been the establishment of a school for midwives in connection with the Philippine General Hospital. It was recognized that the highly trained general nurses graduated from that institution do not meet the urgent need for competent but inexpensive obstetrical service not now available in the islands, and the plan is to create a special class of obstetrical nurses to meet this need. It is estimated that ultimately some 5,000 such nurses ought to be available, to meet the needs in the very many communities where physicians are either absent or insufficient in number. The recent Legislature strongly favored the new plan of a midwives' school, and it is strongly approved by the people as a whole, who constantly see the results of the ignorance, superstition, and inefficiency of the untrained midwives who now practically have charge of all the births in the islands. The Executive Secretary has just sent out a letter inviting each province to send a representative to the new school which will open April 1. The school will give free education, subsistence, and quarters, but not laundry. The province will be called upon to pay the cost of the journey to Manila and return, and a monthly allowance of not less than 10 pesos nor more than 15 pesos. The course of study will continue for one year, at the end of which time the graduate midwife would return to her home and take up practice, since it is believed that only by developing a better class of midwife, and putting it in economic competition with the untrained midwives can the elimination of the latter be brought about. It is expected that some of the graduate midwives will be given official salaried positions as such at their homes, for gratuitous service to obstetrical patients unable to pay therefor. They will also be kept in touch with the Bureau of Health, which will keep them supplied with simple literature on health matters for distribution among the people with whom they come into contact. It is believed that they can do a vast amount of good as missionaries of cleanliness and elementary hygiene and sanitation.

The Bureau of Health educational and exhibit car is meeting with great success in its work. In the first three months of its operation over 100 towns were visited, and lectures in the local vernacular on

health matters were given to audiences aggregating over 75,000 people. A vast amount of sanitary literature has also been distributed. The car, with its exhibit and moving-picture show, has proved very interesting to the people, who are always attracted by anything that savors of amusement, and has brought home to them in a practical way the methods and beneficial results of sanitary work. The car is now in Manila, refitting for work in the province of Nueva Ecija.

A small but sharp outbreak of cholera has occurred in Pinamalayan, Mindoro. The place is somewhat isolated and as soon as news of the occurrence of the disease was received, a coast guard boat with a couple of doctors and half a dozen sanitary inspectors was sent there. The latter returned after a week of work, reporting that the infection had been eliminated. A few days later the American judge there was attacked and died, and a second sanitary detachment had to be sent down. The large family of the deceased American was brought to Manila, and all found to be cholera carriers. This is the season when cholera usually practically disappears, and such instances as these show clearly how the infection can be bridged over from one rainy season to another, to light up a new epidemic at that time. Cholera has also occurred in Zamboanga, which is more than a week's sail from any cholera-infected port, and the outbreak there must have resulted from an infection introduced by a carrier. The importance of carriers in the spread of the disease cannot be overestimated, and from what we already know of the period in which the infection can be harbored by apparently healthy people, it could readily survive a trip from Asia to the United States, and gain entrance thereto in the bodies of healthy persons. No security can be entertained in respect to the introduction of cholera infection unless all persons from cholera-infected ports are bacteriologically examined and found negative. This looks like a large task, but in practice it is not if the work is well organized. And, of course, the cost of keeping up a little extra laboratory equipment and personnel is utterly insignificant beside the necessity of keeping the disease outside the United States. Persons, not things, are responsible for the transmission of cholera infection in the vast majority of instances. And the world has become so small lately, through improvements in rapid transit, that cholera infection anywhere is not a matter of unconcern to health officials in the United States.

A considerable amount of opposition has developed against continuing the sanatorium of the Antituberculosis Society at San Juan del Monte, which is located in buildings in close relation to the old Deposito, or reservoir, for the Manila water supply. Some fifty or more tuberculosis cases are constantly under treatment there, and the necessity of enlarging and repairing the accommodations has raised the question of removal. Dr. Angeles, as chief physician for the society, has been investigating the question of accommodations elsewhere, and the hotel at Antipolo seems to have many advantages. Antipolo is high and cool, and only a short run from Manila. The hotel has not proved a paying investment and could probably be secured at a very reasonable cost. However, the people of Antipolo, which is a great religious center at certain seasons of the year through pilgrimages to the shrine of the Virgin of Antipolo, have raised strong objections to the location of a tuberculosis hospital in their community, and the matter has become one of local politics. The people of Antipolo believe that such a sanatorium would deter many persons from visiting the shrine, to the material financial disadvantage of their community. It appears now as if the opposition would be sufficiently strong to prevent the project.

Dr. Burdette, who has been in the islands many years, and has been physician-in-chief of St. Luke's Hospital, operated under the auspices of the Episcopalian Church, has recently returned to the United States for an indefinite period, by reason of failing health. The hospital authorities have named Drs. James E. Reed and Strahan as attending physicians in his place, and Dr. Reed will take up his residence in the hospital. Dr. H. E. Stafford has been appointed surgeon-in-chief.

4. Varieties of the Gold Sol Test (Lange) in Several Loci of the Cerebrospinal Fluid System: A Study of Twenty-eight Autopsied Cases. H. C. Solomon and E. S. Welles.
5. A Study of Leprosy: With Especial References to the Pulse and Temperature. J. A. Honeij.

1. Dispensaries.—S. S. Goldwater reviews the progress which has been made in dispensary work, which progress consists in the increasing number of individuals treated and in the improvement in methods. In order to reach maximum efficiency a dispensary should be attached to a hospital. Social service work is an indispensable part of the modern dispensary activities. Clinical team work, a valuable feature of the well-organized dispensary, is not available for the patient just above the poverty line. The Boston Dispensary, however, has made a beginning with its self-supported evening clinics.

2. Care of Prospective Mothers.—A. B. Emmons, 2d, states that the problems of maternity and its relations with society are enormous. Scarcely a patient comes to the maternity clinics to-day who is not worried by some social difficulty added to her physical burden. Such problems as illegitimacy, drunkenness, and desertion are frequent, while improvidence, unemployment, and a too small budget are the usual state. The pregnancy clinic attempts to meet these difficulties through the organization and cooperation of the nurses and social workers. Pregnancy care is preventive medicine as applied to obstetrics, *i.e.* the utilization of every known means to keep the prospective mother well and strong, to foresee and forestall dangers, and intelligently to provide for confinement. This may be merely proper care in the home at a minimum expense for the normal case, or the best skill available in a hospital for averting tragedy. Preventive obstetrics thus includes a wide knowledge of the anatomy, physiology, psychology, and sociology of the patient. To obtain the greatest efficiency in pregnancy care there must be cooperation of the doctors, nurses, milk stations, hospitals, boards of health, and the patients and their families.

3. Perforations from Swallowed Foreign Bodies.—F. S. Watson reports a series of six cases of perforations of the stomach and intestine from foreign bodies that have been swallowed. In the reported cases of foreign bodies ingested perforation has occurred in about 8 per cent. One point noted is that perforation has taken place in the bowel in a few instances after

the foreign body has passed through and out of the gastrointestinal tract, seemingly without having inflicted any injury. In these cases the subsequent perforations have been produced as the result of an ulcerative process. One of the factors determining the detention of foreign bodies is a narrowing or constriction of the bowel. The most frequent sites of perforation are in or near the right iliac fossa. Two points which have especially interested the author in connection with this subject have been: The difficulties of making a correct diagnosis owing to the absence of information of a foreign body having been swallowed and the immunity to injury of certain persons who swallow without harm almost anything they can take into their mouths while others cannot swallow even a bristle without having a perforation of the stomach or intestine result.

4. **Cerebrospinal Fluid and the Gold Sol Test.**—H. C. Solomon and E. S. Welles state that their work with the colloidal gold test demonstrates that the composition of the cerebrospinal fluid in the various cisternæ and spaces of the cerebrospinal axis may differ, and that therefore in all probability there is not a free circulation or exchange of the fluid. They have further proved that the examination of the albumin content of cerebrospinal fluid obtained by lumbar puncture is not in all cases a true indication of the condition existing higher up. What is true of albumin is probably true of other substances, particularly the Wassermann reaction, as the Wassermann bodies are probably contained in the globulin.

5. **A Study of Leprosy.**—J. A. Honeij concludes that leprosy is an infection by a specific organism capable of causing marked changes and capable by itself of producing suppuration. Surface lesions are constantly associated with secondary infecting organisms—streptococci, staphylococci, and other bacteria. These are in large part the cause of sloughing and disfigurement. Leprosy bacilli are found in the blood stream and not necessarily during febrile periods only. The infection is general. In advanced cases lesions are numerous and bacilli are present in enormous quantities. If toxic substances are present in however minute a quantity, profound infection during the course of the disease will probably be capable of producing sufficient toxin to give rise to the "toxic-febrile" attacks. They occur at irregular intervals depending upon the state of the patient and stage of disease and upon the number of lesions, as well as the presence of secondary infecting organisms. The attacks occur principally in the advanced stage and tubercular form and, from the author's experience, not in the anesthetic cases. The constitutional symptoms produced are fever, rapid pulse, malaise, prostration, headache, pain, nausea, vomiting, chills, and nervous disturbances, such as anxiety, depression, and delirium. This train of phenomena is indicative of an infection.

10. Bacillus Bulgaricus in Diabetes Mellitus. P. Horowitz.

1. **Plastic Surgery in Treatment of Malignant Disease.**—W. S. Bainbridge first outlines the history of plastic surgery which was practised by the Hindus two thousand years ago. The punishment of nose cutting which was inflicted upon the inhabitants of a conquered city stimulated attempts to repair the mutilation, which attempts, curiously enough, were delegated to the tile makers. Tagliacozzi of Bologna established the art of plastic surgery upon a firm footing. The author discusses plastic surgery particularly as it is applicable in cancer under the two divisions—corrective or restorative repair and palliative repair. The former may be resorted to in precancerous conditions and in the physical defects remaining after the removal of a cancer. Palliative repair is applicable in irremovable cancer. In many cases in which it is impossible to rid the patient of all macroscopic evidences of cancer, great relief may be afforded, both physically and psychically, by clearing off the affected area, fulgurating, or otherwise cleaning up the ulcerating surfaces, and then applying autoplastic or heteroplastic flaps or skin grafts to the denuded area. It is sometimes possible to succeed in getting very large areas covered in this manner. It is obvious that the patient is far more comfortable afterward than would have been possible with an ulcerating open wound. And these patients sometimes remain "clean" so far as the external cancer is concerned, perhaps dying of internal cancer without knowing, except in obstructive cases, that they have not been entirely cured of the disease. Internal cancer is, as a rule, a far more merciful affliction than external cancer, and the comfort which the patient experiences with the covering over of the cancerous area is compensation enough for the care expended in the plastic operation.

2. **Splenectomy.**—A. A. Kerr states that the indications for this operation are: (1) Injury or prolapse. (2) Certain cases of movable spleen. (3) Sarcoma or lymphosarcoma in the early stages. (4) Simple hypertrophy, with or without cirrhosis. (5) Cysts. (6) Hydatid diseases. Localized tuberculosis of the spleen. (7) Splenic anemia with splenomegaly. In leucocythemia, the splenomegaly being part of a general systemic condition, splenectomy is contraindicated.

3. **The Gastric and Pain Crises in Tabes.**—J. Byrne believes that the gastric and pain crises of tabes seem to be primarily the result of a banking of potential in the neurons distal to the lesion, *i.e.* in the ganglion cells. This banking of potential goes on with greater or less rapidity, depending on the activity of the metabolic processes, the character of the food, mode of life, atmospheric conditions, the degree of completeness of the block in conduction at the site of the lesion, etc., until the obstruction is no longer able to prevent the passage of impulses inward toward the cord. Then individual neurons, one or any number at a time, commence discharging, and impulses reach the brain, causing pains referred to the peripheral areas of distribution supplied by the discharging neurons. In the case of the vagal and glossopharyngeal neurons the afferent impulses impinge with greatest effect upon the vomiting center, causing nausea, vomiting, and the distress that accompanies them. After repeated successive discharges the cell bodies become fatigued, the potential falls below the point necessary to force a passage at the site of the conduction block, and the attack ceases for a time.

5. **Trichomoniasis of the Intestine.** — K. M. Lynch points out that trichomonas is a definitely pathogenic microorganism. The intestinal form produces a mild enteritis manifested by an intermittent diarrhea. Infection by this organism may occur by mouth or by rectum, more naturally by mouth, from active forms in rabbits, but probably from encysted cells in human be-

ings. The duration of the infectivity of water containing either active trichomonads or the encysted is probably not long. The form of the cell may be so altered by environment as to render immediate recognition difficult. This organism is capable of artificial cultivation. It multiplies by direct cell division; this, with the transformation into the encysted form which may again become active, constituting the life cycle of the organism. Rabbits are susceptible to experimental infection by trichomonas.

6. **Postpartum Retrodisplacement of the Uterus.**—T. H. Cherry notes that postpartum retrodisplacements of the uterus are far more frequent than is generally thought, and that the discovery of this complication would be made more often if the patients were followed throughout the entire period of involution by the obstetrician and if he made frequent bimanual examinations to the sixth or eighth week. The etiological factors are relaxed uterine ligaments, attempting to hold a heavy, freely movable uterus in proper position, while an increase in intraabdominal pressure produces a posterior displacement. A great many displacements can be prevented both during the lying-in period and later by the institution of postural treatment and the hastening of involution. The treatment is the immediate reposition of the uterus and its maintenance by whatever procedure is most applicable to the period and state of the pelvic structures undergoing involution. The results of the prevention and conservative treatment of retrodisplacement are most satisfactory, and if instituted in time very few patients are subjected to permanent pessary life or need come to operation.

1. **Landau's Color Reaction in Syphilis.**—J. A. Kolmer states that Landau at first used iodized petrolatum for the test, prepared by mixing 5 drops of tincture of iodine in 10 c.c. of paraffin oil. To 0.2 c.c. of the serum was added 2.5 c.c. of this reagent and the test tube set aside in a dark place for from five to fifteen hours. Syphilitic serum, it is claimed, decolorizes the mixture, while the color persists a reddish yellow with normal serum. Later the technique was modified and a 1 per cent. solution of iodine in tetrachloride of carbon employed. To 0.2 c.c. of the fresh, clear serum is added 0.01 c.c. of the iodine reagent; they are well mixed until all color disappears from the reagent and then set aside in a dark place for four hours at room temperature. With the serum of a syphilitic the fluid is a clear, transparent yellow; with a nonsyphilitic serum the fluid becomes a whitish gray and is opaque. The author concludes that of eleven serums of persons and four of normal rabbits and dogs reacting positively, and of ten reacting negatively in the Wassermann reaction, the tests with Landau's iodized petrolatum were entirely unsatisfactory. Both normal and luetic serums alike were found to produce partial decolorization of the reagent, and complete decolorization was likewise observed with both normal and luetic serums. The results with active and inactivated serum were practically similar. Cerebrospinal fluids of both syphilitic and nonsyphilitic persons tested with iodized petrolatum produced similar results in that both alike caused little or no change of the reagent. With the iodine in tetrachloride of carbon reagent the results with fresh active serums after standing four hours at room temperature, as directed by Landau, were as follows: Of seventy-four serums giving a positive Wassermann reaction, fifty-three, or 71.6 per cent. gave a positive iodine reaction. Of sixty-one serums giving a negative Wassermann reaction, eighteen, or but 29.5 per cent., gave a negative iodine reaction. As based on the Wassermann reaction, the iodine test yielded about 70 per cent. false positive reactions with Wassermann negative serums. The error of the iodine test, therefore, not only is in the low percentage of correct positive results, but is especially evident in the high percentage of false positive reactions with nonluetic serums. With cerebrospinal fluids the iodine reagent produced no visible changes, irrespective of whether the fluids were from normal or luetic persons.

6. **X-Ray Treatment of Deep-Seated Cancer.**—G. E. Pfahler believes that if malignant disease can be completely removed it should be dealt with surgically. Each operation for malignant disease should be followed by postoperative treatment. The extent and character of this postoperative treatment will depend on the location of the disease. Where there is an absolute necessity for delay in operation from some other cause the patient should be treated by means of the *x*-rays, and this treatment should be directed toward the glandular area particularly. Inoperable cases should always be given the benefit of the rays. Some of them will be removed and others made operable. Such treatment should be instituted at once and not as the patient approaches a dying condition. Local recurrences yield to *x*-ray therapy fairly well, and some of these patients can be made permanently well. Metastatic carcinoma, even when it affects the bones, has been shown to heal in at least one case reported by the author.

9. **Action of Opium Alkaloids on the Coronary Artery.**—D. I. Macht concludes from his experiments that of the principal opium alkaloids some affect the coronary circulation markedly, others slightly, and still others not at all. Morphine produces a mild dilation of the coronary, codeine a very slight one, narcotine and papaverine a very marked one, and narceine and thebaine none at all. A combination of morphine and narcotine produces a much lesser relaxation of the coronary artery than that produced by each of them individually. This action of the opium alkaloids has been studied in three different ways and probably holds good in the clinic. It is hoped that these observations may conduce to a more rational therapy of cardiac conditions.

10. Memorandum on the Treatment of the Bacterial Infections of Projectile Wounds. F. F. Burghard, Sir W. B. Leishman, Sir B. Moynihan and Sir A. E. Wright.

1. Wound Infections.—Sir A. E. Wright, in the third contribution on this subject, points out that the Listerian method is of little avail in the treatment of projectile wounds, for these are infected before they are seen by the surgeon. Prophylactic applications of antiseptics give good results only when the microbes are accessible. In projectile wounds the microbes have been carried down deep into the tissues and lie on the inner face of a torn and ragged track blocked by blood-clot and hernia of muscle. The ordinary antiseptics used in wounds have practically no penetrative power. Although the washing out of the wound with antiseptics reduces the number of bacteria in the accessible portions of the wound, nevertheless the serosaprophytes left behind multiply rapidly. The wound fills up again with pus, and in spite of frequent redressings the tryptic action of the pus dejects the granulations and skin surfaces and bacterial poisons are absorbed into the system. The psychological method of treatment is offered by the author as a substitute for the so-called antiseptic method. Where there is an abscess sac or a closed cavity containing pus this must be laid open and an outlet for the discharge must be provided—if possible in the most dependent part. Where an infection has spread diffusely in the tissues free incisions must be made; and where these incisions pass through infiltrated tissues they must be carried from sound skin to sound skin and all the way down to the healthy structures underneath; and here hot fomentations should afterward be applied. Lastly—and this is one of the teachings of the present war—when amputating through infected tissues unrestricted drainage must be provided either by leaving the wound unsutured, or, in cases of gas phlegmon, by reverting to the medieval method reintroduced by Fitzmaurice-Kelly of cutting the limb squarely across at the same level and dispensing entirely with flaps now deemed so essential.

In the treatment of infected wounds one should employ an agent for powerfully increasing the outflow of lymph. This can be effected by the application of hot fomentations or by the introduction of ether into the wound. But better than either of these, because it it is more continuous in its action, and because it renders the lymph incoagulable, and also because it represses emigration, is the lymphagogic application which the author has been recommending now these many years back. This consists of a 5 per cent. solution of common salt mixed with ½ per cent. of citrate of soda. This brings into play osmotic forces and "draws" the lymph out of the walls of the wound by a *vis a fronte*. The citrate of soda is added with a view to decalcify and render incoagulable the outflowing lymph. This lymphagogic solution has in this war proved itself preeminently useful. When brought into application upon a dry and infiltrated wound or a wound that is foul and covered with slough it resolves the induration, brings back moisture to the surfaces, and cleans up the wound in a way that no other agent does. Applied in gaseous gangrene in the form of a wet dressing to incisions which have been carried down into infected tissues it causes lymph to pour out of the wounds and arrests the spread of the infection. And again, applied in gaseous gangrene to an amputated stump in cases where it has been necessary to leave infected tissues behind, it reverses the lymph stream and draws out the infected lymph—saving life in almost desperate conditions.

4. Treatment of Gunshot and Shell Wounds.—H. B. Whitehouse, adopting Wright's recommendations, has treated a series of shell and gunshot wounds of varying degrees of severity by the application of hypertonic saline solution. The results obtained were sufficiently convincing to prove the correctness of Wright's views. At the same time the degree of lymph lavage produced by a saline solution was not great, and although sepsis diminished and wounds healed, the important factor of time was not sensibly diminished. It appeared to the author, therefore, that even better results were possible by employing a solution of greater osmotic power. He therefore had a solution of liquid glucose prepared containing sufficient carbolic acid to have a strength of 1 in 80. This solution was applied directly to the wound surfaces and by means of plugs was carried into the recesses of the same. In a few hours sufficient lymph was exuded from each case to saturate the whole of the wool and bandage covering the part. Coincidentally the purulent character of the discharge changed, and in a day or two a healthy granulating surface remained. The cases so far treated by carbolized glucose dressings include severe compound fractures and large lacerated wounds of the extremities, some involving the elbow-joint and necessitating excision of the joint. One case of shell wound of the cranium exposing the dura mater and injuring the superior longitudinal sinus was also so treated. All of those patients made a rapid recovery and were ready for transfer to England at the end of seven days.

7. On Wound Infections; and on Some New Methods for the Study of the Various Factors Which Come Into Consideration in Their Treatment. (Part III.) Sir A. E. Wright.

2. Gastric Ulcer.—C. Bolton adduces clinical and experimental proof to show that the chief damaging factor in this condition is the acid of the gastric juice which acts upon the wall of the stomach both as an irritant and as a necrotic agent. Poisons circulating in the bland lower the resistance of the mucous membrane to the digestive action of the gastric juice. Hyperacidity increases the destructive action, as shown experimentally in the monkey, by a more or less diffuse gastritis, by definite local patches of gastritis, and by follicular ulceration.

3. Gastric Analysis.—T. Heaton finds that the interpretation of the figures obtained by gastric analysis after a test meal is, by reason of the number of factors involved, a matter of great complexity. Any additional means of standardizing results is therefore desirable. Such means is afforded by adding to the meal a fixed proportion of some inert substance, such as urea, whose proportion can be estimated subsequently in the gastric content. It is then possible to arrive by calculation at an approximation to the figures for the actual composition of the secreted gastric juice, as opposed to those of the mixture of this with the remnants of the fluid of the meal. By this method it is possible also to eliminate the disturbing influences of an abnormally rapid or an abnormally slow rate of emptying of the stomach into the duodenum. The conditions of hyperacidity and of hypoacidity can in that case, the author says, be differentiated from those respectively of hypersecretion and hyposecretion.

Satisfaction of the Protein Requirement in War.—Salkowski refers to estimates that the protein consumption per capita in Germany before the war was 92.9 gm. per diem. Of this amount about 25 per cent was obtained from abroad. These figures refer to perfectly utilizable protein. It has been claimed also that they represent a luxus consumption, due to the great amount of animal food eaten by those who can afford it, but that the amount consumed is within physiological limits, and therefore diesirable. The author dissents and claims that any excess consumption of protein is not desirable, save in the mind of the dealer in meat. If the German depends on the home markets his daily per capita requirements will be 67.2 gm. The actual requirement has been computed at 64.6 gm., so that Germany can really supply enough protein for every one. Even this figure may be too high, as Chittenden's work gives the minimum average requirement as 51 gm. At first sight this figure seems to be as unnaturally low as the 80 to 90 gms. of Pflüger, Bohland and Bleibtreu seem unnaturally high; for the average between the two is close to the amount discussed originally. On the other hand very recent work by German investigators appears to show that even Chittenden's figures are too high. The experiments of Hirschfeld, Hindhede and others have shown that in certain subjects during the test period, and with certain foods, the protein used was but 44.36 and even 25 gms. The author obtained as a figure 42.41 gm. The older experiments of feeding dogs on the low protein diet sufficient however to prevent nitrogen waste, showed that in time the animals developed severe general symptoms, diminished resistance to disease (tuberculosis). These finds gave rise to the belief that rich protein feeding gives correspondingly good results. This theory has remained a theory but is supported by the fact that a subject who consumes a minimum of protein and makes up the total requirement with starch and fat burns up far more food units than one who has a good protein fraction in his diet. In other words high protein and low protein both have drawbacks. The poor man must get his protein from the cheaper foods. War bread is poor in it, as are also potatoes. Skim milk and skim cheese are rich in protein, cheap and utilizable. Legumes are rich in protein, cheap and much less utilizable (30 or 40 per cent of the contained albumin goes to waste!); but this state of affairs is easily obviated by preparing flour from beans, peas, etc., the waste being about 12 per cent in this form. These figures refer to dogs, for these flours or meals do not seem to have been tested in man. A desideratum is therefore a bean bread which should be far more valuable than potato bread. But while peas and beans are normally cheap per se milling will add to their cost, and they will be scarce until the next harvest. After drying and milling they can be used as an adjunct to rye meal for the preparation of bread, etc. The author alludes briefly to the blood of slaughtered animals which can be used on a much larger scale than at present. The use of blood soup seasoned with vinegar (the blood cooked with dried fruit) could be made more general. The author feels quite certain that blood is the ingredient which gave the black hue to "Spartan broth." To prepare blood for food, take coagula produced by heating the dilute fluid, dehydrate with alcohol or ether, dry in the air, and grind into a fine powder. A certain feeling of grit cannot be eradicated. and the cost of production is considerable; so that dried blood will hardly be a popular article of diet.

Familial Cancer of the Stomach.—Pel of Amsterdam gives a remarkable case of familial cancer in which four generations (the fourth having but two members) are tabulated. Nothing is known of the causes of death in the first generation of four people —for two families intermarried. The second generation showed in one family four cases of cancer, every member being attacked; while of three members of the other family two were attacked. A man of one family married a woman of the other. The man died at 40 of cancer of the stomach, while his wife lived to be 86 and did not develop the disease. This couple had nine children, three of whom died of cancer of the stomach or esophagus. The others are living and well, ages from 75 to 63. The oldest, a daughter, had two children, daughters, one of whom died of cancer. In this family, ten members developed cancer, the majority cancer of the stomach or esophagus or merely "visceral." In three only the cancer attacked the face. More striking in the way is another episode in which in a single family of seven children, five died of gastric cancer. No predisposition was apparent. In the first example there was a marriage of members of badly tainted families. Quite a number of similar cases are related in literature.

March 29, 1915.

Warfare and Alimentation.—Rosenfeld, referring to the English blockade of Germany, quotes von Moltke as saying in substance that Germany will succumb without resistance if her agriculture fails. The situation is reversed to a certain extent in England because even in times of peace her agriculture is by far inadequate to support her. Germany imports food products, but also exports them; for example, she imports wheat and exports rye, so that shortage in wheat does not in the least mean famine. With eggs the case is quite otherwise. Germany imports them normally from Austria and Russia, and Austria will probably be soon forced to consume her own eggs. But the Russian shortage means only that each German individual must reduce his consumption of eggs by an insignificant margin. It is the same with milk and cream. France was exporting 5,000 tons of milk per annum, and the loss of this is practically not felt at all. The 30,000 tons of Russian (Finnish and Siberian) butter cut off mean the loss of about a pound of butter annually per capita. Germany is losing 18,000 tons of beef and mutton tallow from Argentina, America and Australia, and 50,000 tons of herring from England. Legumes from Russia (amount not stated), are forfeited, and 215,000 tons of Indian rice. All breakfast cereals are cut off, but these can be replaced in a fashion, and of coffee there is an immense storage in Hamburg. The real articles which matter are not the preceding but the wheat, rye, barley and oats, potatoes, fats, meats, sugar and fodder. Loss in wheat can be offset largely with excess of rye production. Further, rye cannot be used as fodder, and its utilizability can be greatly enhanced by stronger milling. Finally, rye will readily bear a 10 per cent. addition of potato flour. The combined result is an equivalent of the lost 3,000,000 tons of import wheat, and doubtless an excess over the latter. Germany loses 250,000 tons of import fats which can only be offset by sugar, 600,000 tons. This can be supplied with the greatest ease as Germany excels in sugar production. So great is the latter that the vegetable substances from which it is largely produced can be returned to the

fodder column to help make up the deficit therein. The sugar beet in particular must be cultivated to the limit both for sugar making and fodder. This will also help out the mediocre potato crop of last year, which amounted only to 45,000,000 tons. This is used up as follows: human consumption, 13,000,000; distillation, 4,000,000; fodder, balance. The 1,700,000 tons of barley, aside from the brewing industry fraction, serves as food for man and fodder for beast. As the nutrient value of beer is a subject of dispute, the author advises the direct consumption of barley flour and groats. If beer is brewed we get nourishment for man in the beer and fodder in the refuse; but as already stated, we are supposed to add the caloric value of the alcohol in the beer to the carbohydrate and extractive matter; and this cannot be determined to a certainty. The amount of barley used in brewing should be more or less diminished, and the populace should acquire the habit of slaking their thirst with water. Returning to the potato crop, the fraction used for distillation of spirits should be reduced to the utmost, and the fodder fraction eliminated entirely. In a word the potato must become one of the mainstays in war dietetics and its acreage must be greatly increased. The enormous resistance of the Russian troops in the present war is imputed by the author to the proscription of vodka. German troops despite their mental, psychical, and physical superiority might take pattern by the Russian; for it is rumored that the Germans are anything but abstemious at present. In regard to meat there is a surfeit of cattle and swine with a deficit in fodder. There are more than 20,000,000 head of each kind, as a result of an active import trade before the war. Much fodder has had to be used to for human consumption, while the former large imports of fodder are no longer available. The normal deficit in fodder is from 6 to 8 millions of tons. The only course to pursue is to slaughter a certain number of animals. About 30,000 swine come first, for it requires 4 to 5 kilos of best fodder (potatoes, barley,) to nourish 2 kilos of animals. Hence, this fodder goes directly into human pabulum. From another angle, pork is the best among rivals for human consumption. The cow stands quite apart for it is a milch animal. With her, fodder is converted in part to milk. Hence, the cost to feed swine can be taken over by cattle, with profit, as well as by man. The slaughtered swine can easily be converted into hams, sausage, pickled pork, etc. The author gives the general advice of "waste nothing" and "eat for your actual requirements"—quoting an old saw to the effect that "spare diet imparts strength and full diet weakness."

Deutsche medizinische Wochenschrift.

March 25, 1915.

Experiences of a German in a Russian Prison.—A German surgeon who was captured and sent to Wologda (city) found already 4,000 Germans and Austrians, including women and children. They were permitted to organize among themselves for relief. Some of them had means, while other aid was obtained from the American ambassador at St. Petersburg. Quarters were hired and the indigent were fed, clothed and sheltered. A dispensary, hospital and drug store, were established. The author was kept occupied continually and the days passed rapidly. Diseases due to exposure were very common, and there were also cases of typhoid, scarlatina and measles. Finally smallpox broke out in the city. The Russians are quite indifferent to the presence of the disease and have no compulsory vaccination. The author at once began to vaccinate extensively and but two cases of the disease developed among the prisoners. When a contingent of Austrian prisoners passed through the city three with smallpox were dumped off and placed in the local hospital and 67 more were placed for observation in the tiny local prison, where a few more cases developed. The local prison was in such a wretched condition that the author caught cold and developed pneumonia with transient paralysis of one leg.

Straw Powder as Food and Fodder.—Boruttau refers to a discovery that vegetables can be reduced to a fine powder which could be used for food. Hence it occurred to the author to powder such substances as bran and straw. These were mingled with pure protein matter, largely perhaps to take the place of cellulose and act as food ballast. The idea of attempting to feed soldiers on powdered straw was attacked by scientists like Rubner and by the daily press. It was next thought of as fodder but nothing seems to have been done in this direction

Cancer of the Stomach in a Boy of Nine.—Karl describes a case which seems to be quite unique in literature. The patient had been a physical weakling since birth. At the end of September he began to vomit blood and could retain no nourishment. When first seen he weighed but 28 pounds. So thin was he that a growth at the pylorus could be easily palpated. An *x*-ray was thought not worth while. On December 4 the author operated. The growth was still movable, as large as a child's fist. A wide resection was performed, the duodenal end closed and a gastrojejunostomy performed. Professor Orth confirmed the diagnosis of cancer. The improvement was wonderful. The boy began to ask for food, ate well and when last heard of (March 4) weighed 59 pounds. In theory, by reason of his youth the prognosis should be as bad as possible. The case will be followed up and made the subject of a monograph.

Is There a Successful Treatment for Scarlet Fever? Koch states that during the ten years' experience of a particular hospital in which 1438 cases of scarlet fever were treated, the mortality was 15 per cent. The rate showed great variability. During one period of 6 months there was not a single death. The majority died very early from the general intoxication, the minority later from complications. When plenty of convalescent serum was available its curative power seemed indisputable. This holds good for normal serum which was employed less frequently. The author is certain that the very cases of scarlet fever which end fatally in the first few days can be cured by convalescent serum. The prompt effects seen in this connection far surpass those of antitoxin in diphtheria. As to how far normal serum can replace it remains to be seen. Doses must always be large, the serum must be sterilized, various sera may be combined, it can be given only in a vein, and amphylaxis should not develop.

Hemorrhagic Symptoms in Typhoid Fever.—Braillon and Bax note that apart from the epistaxis which may occur at the onset of the disease and the intestinal hemorrhage due to the ulceration of the bowel, typhoid fever may assume a true hemorrhagic aspect which dominates its clinical course. The hemorrhagic condition may assume two types according as it appears early or late. The early form is the more severe, similar to the malignant hemorrhagic condition occurring in other infections. The later form occurs during defervescence or convalescence in cases which have given no indication of unusual severity. It usually lasts about six or eight days, ending most frequently in recovery.—*Bulletin et Mémoirs de la Société Médicale des Hôpitaux.*

Insurance Medicine.

Life Insurance and General Medicine.—Life insurance medicine is far removed from speculation and theory and for this very reason cannot serve as a guide to bedside medicine where individualization and medical intuition plays so great a rôle: but it is of great value in medical forensic practice in which expert opinions must constantly be given on illness and death, the chances of survival as affecting the value of a life or the prospect of useful existence in the same connection. Florschütz includes all such activities under the head of Life Insurance Prognosis, with reference of course solely to selection. A trained and experienced insurance examiner, therefore, has the qualities which go to make a good forensic expert on all matters in which the future is thus involved. Medical opinions are frequently based on life insurance blanks by medical examiners.—*Blätter für Vertrauensärzte der Lebensversicherung*, Vol. V, No. 6; Vol. VI, No. 1, 1914-1915.

Influenza.—In presenting a paper on this subject before the Life Assurance Medical Officers Association of London, on January 6, 1915, Dr. H. Selfe Bennett states that for years past no cases have given rise to more doubts and difficulties than those in which there has been a past history of repeated attacks of catarrh. Such attacks are sometimes described under the title of influenza, but more often they are put down in the personal statement as ordinary colds, if indeed they are mentioned at all. A patient confined to the house for about a week, whose temperature has subsided to normal, and symptoms of catarrh have disappeared, allowed to go about his daily avocations as cured by the family physician. It has, however, been discovered that catarrhs are dangerous, and it is now recognized that the dividing line between a feverish cold and irretrievable disaster is perilously thin.

There is an intimate connection between the slighter and graver forms of this affection. In the epidemic form sudden onset with prostration of strength has been described as pathognomonic, but unless the attack is immediately followed by other symptoms, such as chronic headache, broken sleep, depression of spirits, apathy and lack of energy, the neurasthenia of which these are the signs, is not considered as directly due to the primary fever. The objective signs of lowered vitality must be sought for; the subjective signs are constantly accounted for in other ways, *e.g.* by worry, overexertion, increasing age, or other "natural causes." Thus one is told that an arrhythmic pulse and a subnormal temperature are habitual, have been noted for years, and are of no importance; the one has been put down to cigarette smoking, and the other to an idiosyncrasy. It may be so, but when this condition is found with a slow pulse of low tension, feeble cardiac action, phosphaturia, broken sleep, and a past history of severe cold, with or without bronchitis, pleurisy, or pneumonia, one is justified in not accepting the explanation as satisfactory. Sometimes we are told of an attack of neuritis or herpes zoster, sometimes of mental depression and lack of energy, with broken sleep or downright neurasthenia. We are shocked to hear of men who until quite recently were working in apparent good health, who have died a few days or weeks later of pneumonia or heart failure, or more luckily have been laid up with appendicitis. Is it unreasonable to connect such definite affections with a previous influenza, although it is not possible to prove the connection? Also, besides the close connection between influenza and the conditions mentioned, affections of the middle ear and appendicitis may follow influenza. However sceptical some may be as to the relation between influenza and inflammation of the appendix or the mastoid, few men of experience will refuse to recognize how often tuberculosis has followed upon such an attack of influenza. True, it may be that compared with the whole number of such cases the proportion that acquire graver and more definite symptoms is probably small, yet it is quite sufficiently large to form an unpleasant percentage of premature claims. In such patients the objective signs are few, while the subjective symptoms are many, though the latter are not naturally emphasized by the candidate for insurance, who will, in fact, deny that he has had influenza while he admits an ordinary cold. Questioned closely he will confess to many of the more definite symptoms, but has, as he says, "cured himself." These are they who, if postponed, go promptly to another office and are accepted without extra premium. If they die a few months or years later the examiner cannot be held responsible for non-discovery of an acute affection, no sign of a tendency to which could have been found at the time the case was examined. For here, as elsewhere so often, it is not the single sign or circumstance that leads to judgment, but the combination of several; it is comparatively seldom that one flaw condemns the man in the high court of insurance, but the conjunction of this and that to form the whole impression. The cases that trouble the examiner are not those of obvious lesions, but those where he finds a collection of imperfections, each perhaps small in itself, but making a total which other examiners may consider insufficient even for rating up, still less for rejection. These are the conditions which lead to differences of opinion among doctors, differences more rife in these days than in former times, when consultations were common.

Accident Insurance.—In an action on an accident insurance policy it appeared that the insured was in the habit of using a nasal douche, which on one occasion he sniffed into his nostrils more violently than usual, thereby drawing streptococcus germs into the middle ear, whence they penetrated through the mastoid bone into the brain, causing spinal meningitis, from which he died. Though the particular inhalation was more violent than usual, it did not appear that it was more violent than he intended it to be, or that there was any shock making him draw a deeper breath than he intended to draw. It was held that, while an unbroken string of causation might be found between the too violent inhalation and the ensuing death, there could be no recovery under a policy insuring against death from injuries effected through external, violent, and accidental means. It is not sufficient that the death or injury be an accidental result of an external cause. The cause must be not only external and violent, but also accidental. Here the external act was not accidental, but exactly what it was designed to be.—Smith v. Traveler' Insurance Company (Mass.), 106 N. E. 607.

Book Reviews.

FEVER. Its Thermotaxis and Metabolism. By ISAAC OTT, A.M., M.D., Professor of Physiology, Medico-Chirurgical College, Philadelphia, etc. Price, $1.50 net. New York: Paul B. Hoeber, 1914.

THE subject matter of this small volume comprises the substance of three lectures delivered before a second-year class of medical students. The first lecture deals with thermotaxis or heat regulation, which is supposed to depend upon four nervous centers: two basal thermogenic centers and two inhibiting cerebral centers. The author has shown experimentally that the chief basal center is the tuber cinereum. In the second lecture he discusses the subject of heat dissipation or thermolysis and states that he has located a polypneic center in the tuber cinereum. This lecture includes also a discussion of the perspiration and its relation to temperature, the internal secretions and temperature, the theory of anoci-association in relation to fever, heat production in normal and hyperthermic conditions, protein fever, and calorimetric studies of malarial fever. These studies are continued in the third lecture, which also discusses metabolism in fever, and the question as to whether fever is noxious or beneficial. Dr. Ott has written an interesting and useful volume.

FEAR AND CONVENTIONALITY. By ELSIE CLEWS PARSONS, Ph.D., author of "The Family," "The Old Fashioned Woman," etc. Price, $1.50. New York and London, G. P. Putnam's Sons, 1914.

A NEW sociological theory is propounded in this volume. The substance of this theory is that "fear of change is a part of the state of fear man has ever lived in" and that "civilization might be defined indeed as the steps in his escape." Conventionality represents a part of man's "system of protection against change he has begun to examine, and his fear lessening, even to forego." The above theory is the text about which the author has written a number of interesting chapters on the following subjects: on not taking to strangers; travelers; hospitality: the guest; hospitality: the host; introductions and disinfectant rites; caste; a postscript on chivalry; acquaintances; presents; calling; entertaining; between the sexes; marriage; in the family; age-classes; concerning ghosts and gods; and an unconventional society. The book is quite an interesting one, being based upon wide reading and scholarship. The author speaks plainly and without a superfluity of words. She finds that after all "human nature is the same the world over." The customs of savages and civilized peoples of remote times and the present are compared and contrasted. Miss Parsons believes that the society of the future will be unconventional, in which event sex itself will be "left free to express itself" rather than being under "any repressive system." "Love making will become part of the art of living and inexpertness in it a subject for jest perhaps, or for lament, but never a virtue to be boasted of or acclaimed."

ABDOMINAL OPERATIONS. Volumes I and II. Third Edition, revised. By Sir BERKELEY MOYNIHAN, M.S. (London), F.R.C.S. Leeds, England. Entirely reset and enlarged, in two octavo volumes, totaling 980 pages, with 371 illustrations, five in colors. Price, cloth, $10 net; half morocco, $13 net. Philadelphia and London: W. B. Saunders Company, 1914.

THE new edition of Moynihan's "Abdominal Operations" scarcely needs an introduction, for since the appearance of the original edition it has been rightly looked upon as one of the most important works covering this particular field. It is based upon personal experience, describes in detail only those operations and methods practised by the author, and frankly sets forth his opinions as to the best way of doing things. This does not always correspond to the popular ideas, but there is usually a good reason given for the author's stand, and we sometimes find ourselves convinced almost against our will that he has the better of the argument. In the original preface is the statement: "I have included only those operations which are common to the two sexes. No gynecological operations are described. The surgery of organs, such as the kidney and bladder, which is partly intraperitoneal and partly extraperitoneal, is not included, nor are the various operations for hernia." We cannot question the author's wisdom in steering clear of the field of gynecology, and the subject of hernia can well be omitted, for we have a surfeit of descriptions of everything pertaining to hernia and are glad to be spared further suggestions of change in technique; but we had hoped that the surgery of the kidney, ureter, and bladder would be incorporated in this edition, for operations upon those organs, particularly the kidney and ureter, are certainly common to both sexes.

The work as a whole is divided into five sections: I, General Considerations. Here we find remarks upon the preparations necessary in abdominal operations, the conduct of the operation, and the after-treatment of the patient; complications and sequels of abdominal operations; the surgical treatment of acute peritonitis, and other subjects. Section II, Operations Upon the Stomach. In this section we have one of the most valuable portions of the work. It covers a field of which Moynihan is eminently qualified to speak, since he was one of the epoch makers in the recognition and surgical treatment of gastric, and especially duodenal, ulcers. Besides the consideration of these subjects we find chapters on hourglass stomach, gunshot wounds of the stomach, two interesting chapters on cancer of the stomach, and several others covering the various operative procedures. Section III, Operations on the Intestines. This covers all the usual operations on the small and large intestines, and takes up certain special topics, such as intestinal obstruction, embolism and trombosis of the vessels of the mesentery, intestinal perforation in typhoid, intestinal exclusion, short-circuiting, etc. Section IV deals with the surgery of the liver, gallbladder and bile ducts; Section V with the pancreas and spleen.

In all parts of the work we find the subjects presented thoroughly. The surgical anatomy, pathology, diagnosis, steps of the operation considered best by the author, after-treatment, complications and their treatment, are all discussed as fully as the subject under consideration requires. While the work refers almost constantly to the contributions of surgeons from all parts of the world, the personal element is seldom lacking, thus giving added charm to a work that is well-nigh invaluable from the text-book point of view. A final word of appreciation of the unusually excellent illustrations must be added.

PRAKTIKUM DER KLINISCHEN CHEMISCH-MIKROSKOPISCHEN UND BAKTERIOLOGISCHEN UNTERSUCHUNGSMETHODEN. Von Dr. M. KLOPSTOCK und Dr. A. KOWARSKY in Berlin. Dritte Auflage. Price, 8 M. Berlin und Wien: Urban & Schwarzenberg, 1915.

THE third edition of this hand book has been quite thoroughly revised and somewhat enlarged. This is especially noticeable in the chapter on the examination of the blood, which includes a description of the Wassermann and Abderhalden reactions. In the chapter on the urine several of the methods largely used in this country, notably those devised by Benedict and Folin, and the urease method for the determination of urea are omitted. Most of these methods are of approved value and are distinctly better than those given in this volume. On page 15 there is an error in quoting a table of the sugar reactions of the Gram-negative cocci from Kolle and Hetsch in that levulose should be written instead of lactose and the *Diplococcus flavus* should be noted as fermenting levulose. The book is an extremely handy one, however, compressing as it does a great number of methods in a very small space, and would be a valuable one to the laboratory worker in spite of its omissions.

TEXTBOOK OF MASSAGE AND REMEDIAL GYMNASTICS. By L. L. DESPARD, Member and Examiner Incorporated Society of Trained Masseuses. Second edition. Price $4.50 net. London: Oxford University Press, Henry Frowde, Hodder & Stoughton; New York: Oxford University Press, 1914.

OVER half of this volume of about 400 pages is devoted to anatomy which is modified somewhat to meet the requirements of the masseur and movement cure specialist. Much space is devoted to the bones and joints, muscular insertions, and group muscles; the vessels, nerves, viscera, etc., receiving much less, though ample, consideration. The technique of massage and Swedish movements is followed by a treatise on the conditions which benefit most from the application of these resources and how to treat them. There is a brief account of medical electricity as used by the masseur. In her preface the author announces that she has in this edition substituted the Swedish classification and nomenclature for the British terms used in the first edition. The work contains over 200 illustrations. Although designed solely for the masseur, it contains much of interest to the medical man.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

109th Annual Meeting, Held in Buffalo, April 26-29, 1915.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 798.*)

SECTION ON PEDIATRICS.

Wednesday, April 28—Second Day.

DR. JOSEPH ROBY OF ROCHESTER, IN THE CHAIR.

The Remote Effects of Bad Feeding.—Dr. FRANK VAN DER BOGERT of Schenectady read this paper. He stated that more and more importance was being attached to the part played by the gastrointestinal tract in the production of ill health. To imperfect metabolism might be attributed lack of vigor, wasting, muscular weakness and incoordination. Most of the functional disorders of childhood were dependent upon gastrointestinal toxemia. Educators were beginning to realize that naughtiness at school was indicative of disturbed health. Even vascular and functional disturbances of the eye might be dependent upon disturbed metabolism. Recognizing the important part played by digestive disturbances in the ills of childhood, Dr. van der Bogert had studied 200 cases taken from his records in respect to their dietetic history during infancy and later during childhood. Of course these 200 children were all ill. Of this number 77 or 381.2 per cent. had been nursed for one year or longer; of these 77, 66 showed symptoms of chronic indigestion and 40 gave evidence of toxemia, including perverted digestion, disturbance of sleep, functional nervous disorders and chorea. In a paper read before this society last year he had shown that there was some connection between growth and recurrence of adenoids and a bad dietetic history and it was suggested that prolonged nursing was a factor in the production of adenoids. His records showed that 60 cases having adenoids, 24, or 40 per cent., were prolonged nursers. Of 55 cases of urinary incontinence, 17, or 31 per cent., had been nursed one year or longer. Prolonged nursing meant, as a rule, carbohydrate excess, since the nursing was usually in addition to other food, between meals and at night. More than 50 per cent. of the cases showed gross dietetic errors. These dietetic errors might be in the direction of proteid excess, fat excess or carbohydrate excess, though the latter was by far the most frequent. Proteid excess was rare, there being only two cases that could be considered excessive meat eaters and only two that consumed excessive quantities of milk. A study of the series with reference to indican in the urine made it safe to conclude that the presence of even large amounts of indican were not indicative of any specific dietetic excess, but rather of a general dietetic disturbance. The excess of indican seemed to originate in the decomposition of proteid matter and the condition seemed to be proteid intolerance brought about by intestinal catarrh rather than proteid excess. Certain skin lesions, such as urticaria and eczema seemed to be associated with indicanuria. The results of the ingestion of large quantities of fat were more evident in infancy than in later childhood, when they were manifested by such conditions as acidosis, recurrent cyclic vomiting, recurrent bronchitis and the effects of excess directly upon the digestive tract. The writer considered somewhat at length the carbohydrate excesses and emphasized especially the difficulty of controlling them. In speaking of the relation of dietetic errors to adenoids, he said that the invariable history of gross dietetic errors in association with adenoids and enlarged tonsils could not be disregarded; of 60 adenoid cases, over 58 per cent. gave such a history. Urinary incontinence was also frequently associated with carbohydrate excess; 38 out or 55, or 69 per cent., of the cases of enuresis gave a history of having consumed large quantities of sugar and starch. Indican was present in only 13 out of 55 cases of enuresis. Of 10 cases of enuresis in which the stools were examined, eight showed undigested starch. The exudative and lymphatic diathesis, though no doubt to a certain extent congenital, were undoubtedly due to the inability of the body to utilize necessary elecents of food and were dependent on faulty metabolism. In his experience fatal cases of scarlet fever and measles were almost without exception badly fed. Diet was a great factor in the outcome of whooping cough and the practice of feeding immediately after vomiting occurred was a bad one. In conclusion the writer urged a more careful study of the dietetic history of children coming under this attention since in dietetic errors lay the cause of many of the disorders of childhood as well as those of infancy.

Dr. HENRY L. K. SHAW of Albany said that he knew Dr. van der Bogert well and that he was an enthusiast on this subject, but personally he could not agree with him that improper feeding caused all the disorders of childhood. He thought it hardly fair to attribute all the nautiness at school, for instance, to bad feeding. In his opinion eczema was not due to the excess of any one element of food but rather to overfeeding, and one should cut down the amount of food rather than change the proportion of the food elements. He could not agree with what had been said as to the effect of diet upon the mortality of scarlet fever and measles, and he thought that after whooping cough they could not feed the children up too much. At St. Margaret's Hospital they gave the children mixed pertussis serum and those who were exposed to whooping cough did not get the disease. They did not give their children with whooping cough nauseating drugs, but did give them plenty of fresh air and they had had no deaths from this disease. It was well to discuss these matters but it was not wise to say that everything was due to improper feeding.

Dr. THOMAS S. SOUTHWORTH of New York said that with reference to prolonged nursing as a cause of adenoids, Dr. Haskin had read a paper before the Section on the Eye, Ear, Nose and Throat in which he stated that there was an absence of adenoids among the Apache indians and that this was because they nursed their babies so long, and that this was a factor in the proper development of the nose, teeth, and upper jaw. This was a new idea since it was quite generally believed that prolonged nursing produced the results that Dr. van der Bogert had found. Dr. van der Bogert did not lay as much stress on the effects of excessive amount of fat as he should. In older children too much milk might work a distinct injury and it might be beneficial to give skimmed milk or to omit the milk entirely. The reader of the paper spoke of meat as a cause of infection and indicanuria and that indicanuria was only an indication of other disordered processes and not directly to an excess of meat, but he did not speak of egg as a cause of putrefaction and indicanuria. He had several cases in which he was doing away with egg largely, and with good results.

Dr. DEWITT H. SHERMAN of Buffalo said that while these remote effects of bad feeding might be due to an excess of one food element, or to an excessive amount of all elements, it was a good plan in making a diagnosis to try each article of diet and to find which one was badly tolerated by the child; this might be some trouble, but it gave a line upon which to work and to benefit the child.

Blood Coagulation in Infancy.—Dr. HENRY L. K. SHAW of Albany read this paper and presented a simple apparatus for calculating the coagulation time of the blood. He reviewed their present knowledge with reference to the phenomenon of blood coagulation and compared the different methods that had been used for calculating the coagulation time of blood, showing that for various reasons they varied very much in the result obtained. He then presented a simple and inexpensive apparatus which was a modification of that of Dale and Laidlaw. Only one drop of blood was required, and that was taken from the finger or toe after the surface of the skin was cleansed and the first drop of blood discarded. The drop used for calculating the coagulation time was collected in a glass tube about three-quarters of an inch in length and of a caliber only sufficient to permit a shot of the smallest size rolling back and forth. The apparatus then kept the shot rolling in the tube until the viscosity of the blood stopped it, and this measured the coagulation time. Dr. Shaw presented records of tests that he had made on the blood of normal healthy infants and children. The average coagulation time for infants under one year of age for a series of 95 examinations was 3 minutes and 47 seconds; in children between one and two years of age in a series of 35 examinations the average coagulation time was 3 minutes and 54 seconds; between two and three years of age, in 20 examinations the coagula-

tion time was 3 minutes and 58 seconds. He had not yet made calculations as to the differences in coagulation time before and after eating, at different times of the day or when the blood was taken from different parts of the body. To get trustworthy results they had to use the same sized drop of blood in all tests. He believed that a knowledge of the coagulation time of the blood in health and disease would have a definite value.

The Treatment of Disturbances of Digestion in Infancy.—Dr. JOHN LOVETT MORSE of Boston presented this paper. He stated that in discussing this subject he would use the classification of the diseases of the gastro-intestinal tract which they had adopted in the pediatric department of the Harvard Medical School and which was based, as far as was possible, on the etiology of these diseases. These three consecutive divisions of his classification were: (*a*) nervous disturbances of the digestion; (*b*) disturbances of digestion; (*c*) infections. By nervous disturbances they understood those conditions in which the symptoms referable to the indigestive tract were due to abnormal influence transmitted to it from unduly irritable or exhausted nerve centers. The most characteristic symptoms were those due to disturbance of the mechanical functions of the stomach and intestines. In this condition the vomitus and stools showed no disturbance of digestion. Disturbances of digestion might be caused by an excess of anotherwise suitable food, by a food too rich but otherwise well balanced, or by a food containing an excessive amount of one or of several of the food elements. When the fermentative processes predominated the picture of the condition was spoken of as indigestion with fermentation. The term fermentation was here used in its broad sense and included all the changes which took place in the various food elements as the result of the action of microorganisms upon them. The border line between infectious diarrhea and indigestion was rather an indefinite one. Infectious diarrhea was also due to the action of microorganisms, but in this condition the bacteria entered the intestinal wall and produced definite lesions of the wall, which might or might not be severe. In order to treat these disorders of digestion intelligently and satisfactorily the cause of the indigestion must be determined in a given case. Much could be learned of the etiological factor in the individual case by a careful study of the food which the baby was or had been taking. Much more could be learned, however, by a careful analysis of the symptoms, and most by a careful study of the stools. It was in most instances impossible to make a correct etiological diagnosis without an examination of the stools, and while a macroscopical examination might be sufficient in many instances, the microscopical examination was advisable in every instance. This examination was not difficult and could be done in five minutes by any one with a little training and experience. When the disturbance was due to too much food, too rich food, or the excess of one element of the food, the amount of food in the first two instances and the amount of the excessive element in the third instance should be cut down to a lower point than would be suitable for a well baby of the given age, especially was this true of disturbances due to fat. When an individual food element was cut down it was necessary to raise the percentage of the other elements in order to keep up the caloric value of the food. In doing this care must be exercised not to get an excess of the other elements. When the protein was at fault, because of the formation of curds, it was better, instead of cutting down the percentage of protein, to prevent the formation of curds by boiling, by the addition of alkalies, or of citrate of soda, by the use of precipitated casein or buttermilk, or by pancreatization of the food. Drugs were of little or no use in the treatment of simple indigestion. There was practically never a deficiency of hydrochloric acid, pepsin, or rennin in children. In all but the mildest acute cases the intestinal tract should be cleaned out at the beginning of the treatment. For this purpose castor oil was the most useful drug: calomel might be used if there was vomiting, and milk of magnesia in the mildest cases. In severe cases it was advisable to wash out the bowel in the beginning. When the indigestion was chronic, it was advisable to begin treatment with an initial catharsis, since this was a weakening procedure when the baby was in an enfeebled condition. When the disturbance of nutrition was extreme it might take away the baby's last hope of recovery. When the baby was vomiting food should be stopped; if vomiting was severe, the stomach should be washed out. Inunctions of oils were useless in chronic disturbances of digestion. In indigestion with fermentation, which in the vast majority of instances was due to organisms which produced the fermentative changes in carbohydrates and to a less extent in fats, the stools were usually green in color, strongly acid in reaction and odor, and irritating to the skin. In these cases food should be stopped for twelve to twenty-four hours, the intestinal tract cleaned out, and water given freely. It was not safe to continue the starvation longer than twenty-four hours when the microorganism causing the trouble was of the proteolytic type, because the intestinal secretions were protein in nature and provided a suitable culture medium for proteolytic bacteria. There was no objection to a longer period of starvation when the microorganisms were of types that thrived on carbohydrates or fats. In this type of indigestion the object of treatment was the inhibition of the activity of the microorganisms. Drugs and intestinal antiseptics were of little use. The salts of bismuth, preferably the subcarbonate or milk of bismuth, might possibly diminish the severity of the symptoms. The administration of antagonistic bacteria was indicated. Lactic acid bacilli might be given in the form of broth cultures, buttermilk, or modified milk ripened by them. The latter method was preferable since the food could then be modified to meet the needs of an individual infant. Of course lactic acid bacilli should not be given when the disturbance was due to excessive action of the lactic acid bacilli. Again the activity of the microorganisms might be inhibited by a change in the character of the infant's food, since this would change the medium in which the bacteria was growing. When a baby seriously ill with indigestion, with fermentation, showed excessive vomiting, hyperpyrexia, symptoms of irritation of the central nervous system, prostration and collapse, it was advisable to repeat the initial catharsis and withhold food for twelve hours if the condition of the baby warranted it. It was seldom advisable to give coal-tar products to infants to reduce the temperature. It was useless to give drugs by enema. Morphine subcutaneously might be necessary and bromide of soda might be given for restlessness in doses of five to ten grains. Alcohol was contraindicated when these conditions were associated with vasomotor paralysis and lowering of blood pressure. Strychnia was in general the most useful of stimulants, while caffein and camphor were the best quick stimulants.

Experiments with Malt Soup for Institution Marasmus.—Dr. THOMAS S. SOUTHWORTH of New York presented this communication in which he stated that not many months ago he was called upon to assume control of wards containing a considerable number of bottle-fed institutional infants and found himself confronted with the problem of improving their nutrition. The stools of the majority were white and green in color and the infants were losing weight. Careful adjustment of the usual formulas had no appreciable influence and it became evident that it would be impossible to wait the results of further adjustments. Some plan had to be adopted to cut short the losses in weight. Malt soup was selected as offering greater promise of producing results than any other article of diet. No attempt was made to follow stock directions, but the milk content of the malt soup mixtures was adapted to the individual requirements of the infants. The purpose was to substitute for the milk sugar, and possibly barley water of the infants' formulas, carbohydrates in the form of the more absorbable dextrine and maltose contained in the malt soup extract, together with its usual accompaniment of boiled wheat starch for its recognized protective action. Their procedure was to use for each infant the number of ounces of milk or top milk which it would properly receive in an ordinary suitable formula, to add the requisite amount of water and then one teaspoonful each of malt soup extract and wheat flour for approximately each ten ounces of the total food. The mixture was brought slowly to a boil to gelatinize the starch and was then strained, cooled and bottled. In private practice it was often well to cook the mixture for thirty minutes. The malt soup mixtures proved a life saver, or, at least, a life prolonger, in nearly every instance. The prophecy made at the start that the stools would become smooth and brownish within twenty-four hours was, as a rule, fulfilled. Infants that seemed doomed promptly showed moderate gains in weight. Milk and cane sugar, both of which were disaccharides, at times overtaxed the upper part of the small intestine, with consequent disorganization of function, and the substitution for either of these single

disaccharides of mixed carbohydrates, maltose, dextrose, and starch introduced new elements and conditions. Dextrin and starch were polysaccharides and were more slowly broken up. Both the chemical processes and the absorption were spread over a greater length of intestinal surface, bringing into play new ferments and fresh absorptive surfaces. This seemed to explain the action of the malt soup in these cases. Dr. Southworth said it had been his experience that malt soup neither caused nor aggravated vomiting, but rather that vomiting had ceased under its administration. In older children suffering from subacute or acute colitism no food equalled malt soup in its ability to nourish and prevent excessive loss of weight and emaciation. The writer stated that he wished to make it clear that he was not endorsing a single method to the exclusion of all others, but simply to relate a favorable experience with malt soup when breast milk was not available and to call attention to its utility at critical junctures. No claim was made that it would solve the whole vexed problem of mortality among institutional infants.

Recent Observations in the Use of the Soy Bean in Infant Feeding.—Dr. John F. Sinclair of Philadelphia, after describing the plant and giving its history, stated that in this country it had been used largely for fodder or to increase the fertility of the soil, but experiments in the Department of Agriculture showed that its uses might be greatly extended. In China and Japan the beans were used in many different ways for food and the oil was expressed for cooking, illuminating, and lubricating purposes. Dr. John Rurâh of Baltimore had been the first to use it in this country, presenting his preliminary report in 1909. Dr. Sinclair had been experimenting with the soy bean for two years, first employing it because of its high protein and fat content as a weak gruel to replace barley water, tea, and other liquids in gastrointestinal disturbances in an effort to check the losses in weight which occurred so frequently. In this it had proved most efficient. He had used the bean in 74 cases in the wards of the Babies' Hospital of Philadelphia during the past two summers. All the babies were under three years of age and were ill with summer diarrhea. Thirty-four were diagnosed as gastroenteritis, 28 enteritis, and 12 ileocolitis. In 28 cases the condition of the patient on admission was noted as "bad" or "dying," while in 36 it was recorded as "fair" or "good." In this series of 74 cases there were 19 deaths, 11 cases unimproved, and 44 babies did well. Some of the babies gained, as evidenced by improvement in their general condition, character of their stools, and increase in weight. Twenty-eight of the 44 cases gained in weight while in the hospital. Of the 11 cases that showed no improvement all but 2 were fed too short a time to permit of the drawing of a satisfactory conclusion. In no instance had any bad result been noted from the use of the soy bean. Their experience with the soy bean and a careful study of their cases led them unhesitatingly to urge its usefulness in the treatment of summer diarrhea, in various intestinal disturbances, and in marasmus. It was well borne, readily digested and by reason of its fat and protein content furnished the necessary pabulum to nourish the sick infant.

Dr. Irving M. Snow of Buffalo believed that disturbances of digestion in infancy were more often due to congenital weakness of constitution, disturbed function or metabolism than to infection or organic changes. Some babies were made worse by injurious treatment, abuse of laxatives, etc., which certainly emptied the intestine, but which might cause vomiting, irritation hypersecretion of mucus and rapid emaciation. Especially dangerous was the employment of long and frequent periods of starvation on tea, water, or thin cereal gruel. Six to twelve hours was a sufficiently long period of starvation unless fever, vomiting, and diarrhea were unusually persistent. Albumen, milk, and dextromaltose were of high nutritive value; they were free from salt and fermentable whey and seldom caused vomiting or frequent stools. A thin, delicate baby might thus be given a suitable food. Human milk was the best of all curative foods and should be early tried in bad cases of food vomiting, and persistent diarrhea which resisted the usual diets. Even a few ounces daily would arrest emaciation and aid in the digestion of other food mixtures. In treating a baby with serious disturbance of nutrition Dr. Snow advised patience, the use of well-tried foods and the avoidance of too many changes.

Dr. Douglas P. Arnold of Buffalo said that there was no better way of dealing with disturbances of digestion than by preventing them and it could not be too frequently emphasized that the best way to do this was by breast feeding. Of course they could not rely on breast milk for older children. If Finkelstein's classification for alimentary disturbances was well worked out he thought they could treat these cases better.

Dr. Norris G. Orchard of Rochester said he questioned whether in Dr. Southworth's experiment the malt soup stood alone in having effected such a change in the character of the infants' stools. It was rare to observe such sudden changes in infants so perilously near the stage of inanition as described by the reader. It was difficult to picture in such infants any part of the intestinal tract not more or less profoundly diseased or at least lessened in tone so that the discussion as to their permeability by certain sugars or their absorption was based on rather uncertain grounds. Might it not be that the value of the malt soup lay in the combination of maltose, salts, nitrogen, and nitrogen containing compounds and to the variety of dextrines and closely allied substances as suggested by Howland? As regarded the non-production of vomiting, their experience had been quite the contrary so that vomiting had been considered a well-defined contraindication to the use of malt soup. Possibly this was due to faulty preparation or administration. More statistical data in this series would have been helpful. However, Dr. Southworth was to be congratulated that in his difficult branch of work, he had been able to achieve such satisfactory results.

Dr. Carl G. Leo-Wolf of Buffalo said he had been using soy bean ever since Dr. Rurâh had called attention to it. He had used it in about 100 cases in private and dispensary practice where one was likely to get better results than in hospital work. In some cases in which the infants were getting proper mixtures but the limit of starch tolerance had been reached, he had given soy bean with good results. Another use to which they had put this food was to give it to nursing mothers; used in this way it had been a great boon to poor mothers during the past winter. From his experience he believed that in the soy bean they had food that had a great future and would be a great help in infant feeding.

Dr. T. Wood Clarke of Utica said that Dr. Morse had said there was never a lack of hydrochloric acid or of gastric or intestinal ferments. In certain cases of vomiting curds he believed there was hyperacidity and that was the reason sodium citrate acted so well in certain cases.

Dr. George Dow Scott spoke of the slight causes that served to upset the equilibrium of the nervous child and called attention to the fact that other factors such as intervals between feeding and general hygienic conditions entered into these digestive disturbances as etiological factors. The reader of the paper on the soy bean did not say why they should give up wine and whey; he had obtained good results with them. Why could they not use split pea or lima bean soup added to the food formula?

Dr. Morse of Boston said he had been feeling more and more how isolated they were in Boston. He did not think that the speakers had entered exactly into the point of view of infant feeding that was held in Boston. Their endeavor was to try to find the cause of the disturbance of the digestion in the baby, and having determined the cause to give the food best suited to that individual baby's digestive power. They thought they could fit the different elements of the food to the needs of the infant by using percentages in older children; they used the calories and regulated them as carefully as they regulated the percentages in the infants, and hence they did not use stock methods of treatment. What he wished to give was a point of view and not a statement, a point of view broad enough to enable them to take in anything and to leave out anything they found to be wrong, but always to view the case from the standpoint of its etiology.

Can Pneumonia in Children Be Aborted? — Dr. T. Wood Clarke of Utica said that in spite of the investigations of a Cole and a Lamar, of Cruikshank, and of many others, pneumonia remained today as it was in the Middle Ages, a self-limited fever which must run its course. In the present state of our knowledge one was justified in following any signpost which might seem to indicate a possible road to a specific medication of pneumonia. It was for this reason that he related his experience in Utica during the past two years which,

though suggestive, was not convincing. He was called to see a case of pneumonia in a child where masterly inactivity was indicated but where he knew a placebo must be given. Having some hexamethylenamine with him he decided that this would be as good as anything, and it might have some beneficial influence by excreting into the alveoli. He left a mixture containing two grains to the dram, a teaspoonful to be administered every two hours. The results were astonishing and he determined to try this agent again. After citing two typical cases Dr. Clark said that during the past two years in every case of lobarpneumonia or bronchopneumonia he had pushed this agent to the limit and with but one exception the results had been gratifying. In every one of the thirty odd cases of pneumonia in children in which he had used this drug, the temperature had begun to drop within a few hours and in from twenty-four to forty-eight hours the patient was well. His experience had convinced him that the use of this drug early in the disease had in a number of instances shortened the attack and he believed that the physicians of Utica and Central New York were converted to the idea that they were no longer justified in relying on "masterly inactivity" in pneumonia in children. He hoped that his confrères with large hospital services would give this drug a tryout.

Dr. JOHN LOVETT MORSE of Boston said he believed that hexamethylenamine was inert, that it did not possess any activity unless broken up by an acid. If the reaction in the lung was acid it might do good; but in his opinion the reaction in the lung would not be strong enough to have any beneficial effect.

Dr. JOHN PRYOR of Buffalo said he did not think this agent was of value except in the urinary tract and that perhaps its value there had been overestimated; whatever action it had was dependent upon an acid medium. To have any action in the lungs more acid would have to be present than could by any possibility be there.

Dr. SOUTHWORTH of New York said that he believed they would have to consider whether it was really an established fact that hexamethylenamine could be split up only in an acid medium; of course if that fact were absolutely proved then Dr. Morse's view would hold good. Certain genitourinary surgeons employed it in an alkaline medium and believed they got good results. Dr. Clarke's view would of course have to be expressed with reserve; there might be doubt as to whether the cases were really pneumonia.

Dr. JOSEPH ROBY of Rochester said that much of the pneumonia seen in Central New York was of a mild type and ran a mild course. They should try Dr. Clarke's suggestion in adults in hospitals and see if they could cut the mortality from pneumonia. This could demonstrate the value of this agent.
